**Note:** The authors have worked to ensure that all information in this book is accurate at the time of publication and consistent with general psychiatric and medical standards, and that information concerning drug dosages, schedules, and routes of administration is accurate at the time of publication and consistent with standards set by the U.S. Food and Drug Administration and the general medical community. As medical research and practice continue to advance, however, therapeutic standards may change. Moreover, specific situations may require a specific therapeutic response not included in this book. For these reasons and because human and mechanical errors sometimes occur, we recommend that readers follow the advice of physicians directly involved in their care or the care of a member of their family.

Books published by American Psychiatric Association Publishing represent the findings, conclusions, and views of the individual authors and do not necessarily represent the policies and opinions of American Psychiatric Association Publishing or the American Psychiatric Association.

# Introduction

Psychopharmacology has developed as a medical discipline over approximately the past five decades. The discoveries of the earlier effective antidepressants, antipsychotics, and mood stabilizers were invariably based on serendipitous observations. The repeated demonstration of efficacy of these agents then served as an impetus for considerable research into the neurobiological bases of their therapeutic effects and of emotion and cognition themselves, as well as the biological bases of the major psychiatric disorders. Moreover, the emergence of an entire new multidisciplinary field, neuropsychopharmacology, leading to the development of specific agents to alter maladaptive central nervous system processes or activity, was another by-product of these early endeavors. The remarkable proliferation of information in this area—coupled with the absence of any comparable, currently available text—led us to edit the first edition of *The American Psychiatric Press Textbook of Psychopharmacology*, published in 1995. The response to that edition was overwhelmingly positive. In the second edition, published in 1998, we expanded considerably on the first edition, covering a number of areas in much greater detail, adding several new chapters, and updating all of the previous material. Again, the response was positive. We then presented third and fourth editions, in 2004 and 2009, respectively, with updated and expanded

material. These have continued to be very popular, and the past three editions of the *Textbook* have each been followed, after an interval of approximately 2 years, with a distilled *Essentials* volume—in essence an updated but abridged version of the *Textbook* in paperback format.

We now come to the fifth edition of this work, *The American Psychiatric Association Publishing Textbook of Psychopharmacology*. Again, all of the material has been updated, and several new authors and chapters have been added, covering new key areas in the specialty. To aid the reader in absorbing and integrating the vast amount of information presented, we have attempted in all editions to provide sufficient foundational material to support a sound understanding of how drugs work, and why, when, and in whom they should be used.

Each successive edition has understandably become larger as we have attempted to keep pace with the ever-growing body of knowledge in the field. In contrast, over the past 20 years, reading preferences have changed, with handiness and portability now being primary requirements. With this in mind, American Psychiatric Association Publishing decided to apply uniformity to textbook sizes and page counts to bring them into line with the more compact format used for the *Diagnostic and Statistical Manual of Mental Disorders*, 5th Edition (DSM-5). Therefore, this revised, fifth edition of the *Textbook of Psychopharmacology* has been designed to be more accessible, with fewer overall chapters than in the last edition, while still covering the depth of information the reader needs.

The *Textbook* has three parts. [Part I, “Principles of Psychopharmacology,”](#) contains 7 chapters that provide a theoretical background for the ensuing parts. Topics

include molecular biology, neurotransmitters and receptors, genetics and genomics, psychoneuroendocrinology, brain-immune system interactions, pharmacokinetics and pharmacodynamics, and brain imaging.

[Part II, “Classes of Psychiatric Treatments,”](#) presents information by classes of drugs. For each drug within a class, data are reviewed on history and discovery, preclinical and clinical pharmacology, pharmacokinetic parameters, mechanism of action, indications and efficacy, side effects and toxicology, and drug-drug interactions. This section is pharmacopoeia-like, encompassing 38 chapters generally dedicated to individual agents (e.g., paroxetine, venlafaxine, vortioxetine, lurasidone, cariprazine). We include data not only on drugs currently available in the United States but also on medications that will in all likelihood become available in the near future. On many chapters we have invited new authors to provide fresh insights.

[Part III, “Psychopharmacological Treatment,”](#) includes 14 chapters that review state-of-the-art pharmacotherapeutic approaches to patients with major psychiatric disorders as well as those in specific age groups (e.g., pediatric populations, elderly patients) or circumstances (e.g., psychiatric emergencies, chronic pain). Here, too, new contributors provide fresh looks at important clinical topics. Chapters in this section provide the reader with specific information about drug selection and prescription.

Finally, an [Appendix—“Psychiatric Medications”](#)—provides key information on indications (both approved and off-label) and dosages (both adult and pediatric) for individual agents covered in the *Textbook*, presented in a convenient tabular format.

This *Textbook* would not have been possible without the superb editorial work of our managing editor, Rebecca Wyse, who organized the coordination of chapter authors' efforts and time lines. In addition, we wish to thank John McDuffie, Associate Publisher, Acquisitions and Development, of American Psychiatric Association Publishing and his staff for their efforts. In particular, we appreciate the major efforts of Bessie Jones, Acquisitions Coordinator; Greg Kuny, Managing Editor; Tammy J. Cordova, Graphic Design Manager; Rebecca Richters, Senior Editor; and Judy Castagna, Assistant Director of Production Services.

## Basic Principles of Molecular Biology and Genomics

Jiang-Zhou Yu, MD., Ph.D.

Mark M. Rasenick, Ph.D.

In June 2000, it was announced that both a corporate effort and a government consortium had succeeded in sequencing all of the human genome. This was followed by the publication of that sequence in February 2001 ([Lander et al. 2001](#); [Venter et al. 2001](#)). For anyone involved in biology or medicine, these events represented a revolution in the technical and conceptual approach to both research and therapy.

It seems that humans are far less complex than most scientists had previously thought. Rather than having 100,000–150,000 genes, as was once the belief, humans may have only about 20,000 genes. At present, not all of

those genes have an identified function, and it is becoming clear that many gene products have more than one function. Perhaps more important, genes that have been identified in a single cell type may have an entirely different function in other cell types. Some other genes may enjoy a brief and transient expression during the process of embryonic development, only to play an entirely different role in the adult. Truly understanding those genes and gene products will revolutionize all of science, and this may be especially true for psychiatry.

Consider that prior to identification of the genome, psychiatric genomics was limited to studies of chromosomal linkage wherein a putative gene for a disorder could be roughly localized to a given region of a chromosome. This burgeoning understanding of the human genome has led to a rudimentary understanding of genetic variation among humans. In many humans, a single base or single nucleotide is modified, and it is a combination of knowing the entire genetic code and determining aberrations in individuals with disease that will allow the pinpointing of specific genes associated with psychiatric diseases.

Sometimes during a disease process, inappropriate genes are activated or inactivated. Identifying these genes helps to shed light on the disease process and on possible therapy.

At the same time that rapid advances are being made in understanding the genome, rapid advances in molecular biology are allowing the manipulation of genes and proteins in individual nerve cells. The development of molecular and cellular models for neuropsychiatric disease has also permitted tremendous advancement in understanding both the biochemical defects and possible new approaches toward ameliorating those defects.

In this chapter, we present information about genetics, genomics, and the genome, as well as explain modern molecular biology and the investigative methods used in that field. We also discuss pathophysiology, as related to neuropsychiatry and molecular strategy, and introduce findings from studies on the cell biology of the neuron that help us to understand both psychopharmacology and the biology of the brain and mind. Remarkable progress has been made in the 6 years since the publication of the previous edition of this book. Epigenetics has become important to psychiatry and has sparked new understanding of gene regulation as well as new mechanisms for monitoring this. Gene editing has gone from an in vitro phenomenon to a straightforward technique employed in intact mammals. Optogenetics has revolutionized the tracing of neural circuits, and the study of microRNAs has revealed a great deal about the regulatory potential of noncoding regions of the genome. We discuss these advances in this chapter, but we caution readers that the half decade following publication of this book is likely to bring a new tsunami of discovery to be discussed in the subsequent edition.

## **Cell Biology of Neurons and Glia**

---

To appreciate the molecular biology described in this chapter, one needs to understand the aspects of the neurons that process signals that directly or indirectly modify the aspects of the genome described below. Neurons are specialized cells that function to transmit signals to other neurons, muscles, and secretory cells. Neurons

contain four basic domains (Figure 1-1), which serve to receive signals, process and integrate signals, conduct impulses, and transmit signals.

**FIGURE 1-1.** Diagram of a typical neuron.

As described in the text, this neuron is divided into zones for reception of signals (input=dendrites), integration of signals (regulation=nucleus and soma), conduction of signals (axon), and transmission of signals (axon terminal).

The nucleus resides in the cell body (the signal processing domain) and contains the DNA that codes for the genes expressed by neurons. Activation of a given gene results in the generation of a messenger RNA (mRNA), which is then translated into a protein (see below). Although such events are common to all cells, neural cells are unique in some aspects of molecular signaling. Notably, the variety of gene expression is far greater in the brain than in any other organ or tissue. Some estimates are that in aggregate, the brain expresses up to 10 times the number of genes expressed in any other tissue. This does not mean that individual cells undergo a much greater gene expression.

Rather, it suggests an extraordinary heterogeneity among neurons and glia, which allows for a rich regulation when those neurons and glia assemble into the elaborate network of the human brain.

mRNA molecules exported from the nucleus are translated into proteins by ribosomes in the endoplasmic reticulum. Most of the protein production occurs in the cell body, although there is some mRNA in the dendrites as well ([Steward and Wallace 1995](#)). This means that newly made proteins must be transported from that cell body to the axon terminal, a distance as great as 1 meter. These proteins are often packaged in vesicles, and specialized “motor” molecules transport packaged proteins down microtubule “tracks” at the cost of adenosine triphosphate (ATP) hydrolysis ([Setou et al. 2000](#)).

## Essential Principles of Gene Expression

---

### Genes and DNA

The DNA double helix transmits genetic information from generation to generation and is the repository of information required to guide an organism’s development and interaction with the environment. The role of DNA in storing and transferring hereditary information depends on the innate properties of its four constituent bases: the two purine bases, adenine (A) and guanine (G), and the two pyrimidine bases, cytosine (C) and thymine (T). Within the DNA double helix, A is complementary to T, and G is

complementary to C. Each block of DNA that codes for a single RNA or protein is called a *gene*, and the entire set of genes in a cell, organelle, or virus forms its *genome*. Cells and organelles may contain more than one copy of their genome. When “unraveled,” the total DNA of a single cell is approximately 1 meter in length. Such a large amount of genetic material is effectively packaged into a cell nucleus, which is also the site of DNA replication and transcription. Only a small percentage of chromosomal DNA in the human genome is responsible for encoding genes that act as a template for RNA strands; there are approximately 20,000 human genes, but modifications such as alternative splicing and RNA editing may lead to a larger number of proteins.

Among RNA strands, only ribosomal RNA (rRNA), transfer RNA (tRNA), small nuclear RNA (snRNA), and microRNA (miRNA) have independent cellular functions. The most abundant cellular RNA, mRNA, serves as a template for protein synthesis. RNA, like DNA, is composed of four nucleotide building blocks. However, in RNA, the nucleotide uracil (U) takes the place of thymine (T), and RNA is a flexible single strand that is free to fold into a variety of conformations. Thus, the functional versatility of RNA greatly exceeds that of DNA.

Chromosomal DNA contains both genes and more extensive intergenic regions. Some regions of DNA in genes act as the template for RNA, but some regions are responsible for regulatory functions. The distribution of genes on chromosomes is not uniform; some chromosomal regions, and indeed whole chromosomes, are richly endowed with genes, whereas other regions are more amply supplied with noncoding DNA (although some nongenomic DNA codes for miRNA). Regulation of gene expression conferred by the nucleotide sequence of a DNA

molecule is referred to as *cis*-regulation, because the regulatory and transcribed regions occur on the same DNA molecule. *cis*-Regulatory elements that determine the transcription start site of a gene are called *basal* (or *core*) *promoters*; other *cis*-regulatory elements are responsible for tethering different activators and repressor proteins to DNA. There are specific regions of DNA that bind to regulatory proteins. These regulatory proteins may be encoded at any region in the genome, and because they are not coded by the stretch of DNA to which they bind, they are sometimes called *trans*-acting factors. *Trans*-acting factors that regulate the transcription of DNA are also called *transcription factors*.

## DNA Replication

Chromosomal DNA must be replicated to coordinate with cell division. Replication begins at a sequence called the *origin of replication*. It involves the separation of the double helix DNA strands over a short length and the binding of enzymes, including DNA and RNA polymerases. During DNA replication, each existing strand of DNA serves as a template for the synthesis of a new double helix that contains one old strand and one strand that is newly synthesized but complementary. This process is known as *semiconservative replication*. In the process of cell division, each of the 46 double helices is replicated and folded into chromosomes.

## Transcription

Only a fraction of all the genes in a genome are expressed in a given cell or at a given time. These genes undergo the process of transcription, in which an RNA molecule complementary to one of the gene's DNA strands is synthesized in a 5' to 3' direction, using nucleotide triphosphates. Transcription can be classified into three discrete steps: initiation, mRNA chain, elongation, and chain termination. Transcriptional regulation may occur at any step in the process; however, initiation appears to be the primary control point because, in a sense, it is the rate-limiting step. Localization of the transcription start site and regulation of the rate of transcription are essential to initiation. The *cis*- and *trans*-acting factors described earlier in this section all regulate the initiation of transcription.

## Translation

Each mRNA in a cell can code for the primary amino acid sequence of a protein, using a triplet of nucleotides (codon) to represent each of the amino acids. Some amino acids are represented by more than one codon, because there are more triplet codons than there are amino acids. The codons in mRNA do not interact directly with the amino acids they specify. The translation of the individual codons of mRNA into protein depends on the presence of another RNA molecule, tRNA, which has a cloverleaf structure. On the top leaf of the tRNA structure, three nucleotides form a complementary codon, an anticodon, to each mRNA nucleotide triplet. Thus, each mRNA nucleotide triplet can code for a specific amino acid. Each tRNA carries an amino acid corresponding to its anticodon, and when thus "charged," the complex is termed *aminoacyl-tRNA*.

Anticodons of aminoacyl-tRNA bind with mRNA codons in ribosomes. Ribosomes, a complex of rRNA and enzymes needed for translation, provide the structure on which tRNA can bind with the codons of mRNA in sequential order.

Initiation of protein synthesis involves the assembly of the components of the translation system. These components include the two ribosomal subunits, the mRNA to be translated, the aminoacyl-tRNA specified by the first codon in the message, guanosine triphosphate (GTP), and initiation factors that facilitate the assembly of this initiation complex. In eukaryotes, there are at least 12 distinct translation initiation factors ([Roll-Mecak et al. 2000](#)). After the ribosome recognizes the specific start site on the mRNA sequence, which is always the codon AUG coding for methionine, it slides along the mRNA molecule strand and translates the nucleotide sequence one codon at a time, adding amino acids to the growing end of the polypeptide chain (the elongation process). During elongation, the ribosome moves from the 5' end to the 3' end of the mRNA that is being translated. The binding of GTP to the elongation factor tu (EFtu) promotes the binding of aminoacyl-tRNA to the ribosome ([Wieden et al. 2002](#)). When the ribosome finds a stop codon (UAA, UGA, or UAG) in the message RNA, the mRNA, the tRNA, and the newly synthesized protein are released from ribosomes with the help of release factors that also bind GTP. The translation process is stopped, and a nascent protein exists.

It is noteworthy that initiation, elongation, and release factors undergo a conformational change upon the binding of GTP. In this regard, they are similar to the G proteins (both heterotrimeric G proteins and small "ras-like" G proteins) involved in cellular signaling, and regions of

amino acid sequence homology in the GTP-binding domains have been identified ([Halliday et al. 1984](#); [Kaziro et al. 1991](#)).

## Regulation of Gene Expression

---

### Chromatin and DNA Methylation

Biophysics and molecular biology have revealed that chromatin consists of a repetitive nucleoprotein complex, the nucleosome. This particle comprises a histone octamer, with two copies of each of the histones H2A, H2B, H3, and H4, wrapped by 147 base pairs of DNA. In the octamer, histones H3 and H4 are assembled in a tetramer, which is flanked by two H2A-H2B dimers. A variable length of DNA completes the second turn around the histone octamer and interacts with a fifth histone, H1. H2A, H2B, H3, and H4 are variously modified at their amino- and carboxyl-terminal tails to influence the dynamics of chromatin structure and function ([Ballestar and Esteller 2002](#); [Keshet et al. 1986](#); [Kornberg and Lorch 1999](#); [Strahl and Allis 2000](#)). Although chromatin provides structure to chromosomes, it also plays a critical role in transcriptional regulation in eukaryotes because it can repress gene expression by inhibiting the ability of transcription factors to access DNA. In fact, chromatin ensures that genes are inactive until their expression is commanded. In the activation process, cells must attenuate nucleosome-mediated repression of an appropriate subset of genes by means of activator proteins that modify chromatin structure. An activator protein displaces nucleosomes, which permits a complex of proteins

(general transcription factors) to bind DNA at a promoter and to recruit RNA polymerase.

Cytosine methylation at CpG dinucleotides is the most common modification of the eukaryotic genome, which is catalyzed by a family of DNA methyltransferases including Dnmt1, Dnmt3a, and Dnmt3b. CpG islands are CpG-rich regions in the genome, which are often but not always located in the promoter regions of genes and some regulatory elements ([Jones 2012](#)). Methylation of cytosines at CpG inhibits gene expression either by directly interfering with transcription factor binding to DNA ([Ballestar and Esteller 2002](#)) or by recruiting methyl-CpG binding domain proteins, which complex with histone deacetylase (HDAC) to transform chromatin to a repressive state ([Ballestar and Esteller 2002](#); [Keshet et al. 1986](#)). Dnmt1 expression is remarkably high in the embryonic nervous system, consistent with the proposed role for Dnmt1 in maintaining DNA methylation in dividing neural progenitor cells ([Cedar and Bergman 2009](#)).

In addition to alterations in DNA methylation, epigenetic modifications to histone tails are thought to regulate a range of cellular functions, including transcription, replication, chromosome condensation, recombination, DNA repair, and the organization of higher-order chromatin within the nucleus ([Strahl and Allis 2000](#)). Acetylation and methylation of lysine at histone tails are the two most common histone modifications ([Jenuwein and Allis 2001](#)). Hyperacetylation of nucleosomes was strongly associated with transcription, which is considered a hallmark of transcriptional activity, acting to weaken the polar interaction between the negatively charged DNA and the positively charged histone proteins and resulting in a relaxed chromatin state ([Dindot et al. 2009](#); [Ruthenburg et](#)

al. 2007). Integral components of the transcriptional machinery include histone acetyltransferase and histone deacetylase enzymes, which regulate, respectively, the addition of acetyl groups to and removal of acetyl groups from histone proteins.

The effects of histone methylation on gene function and chromatin state are mainly dependent on the specific residue that is modified. Generally, in activated gene regions, there is an enrichment of histone methylation at H3K4me, H3K36me, or H3K79me (Guenther et al. 2007; Heintzman et al. 2007; Steger et al. 2008). In contrast, the enrichment of histone methylation at H3K9me, H3K20me, or H4K27me is implicated in gene inactivation or silencing (Kouzarides 1999; Ruthenburg et al. 2007). Studies also revealed that the degree of histone methylation plays a role in gene expression activity. The tri-methylation at residues of H3K9, H3K2, and H4K20 is associated with transcription repression (Barski et al. 2007; Mikkelsen et al. 2007; Vakoc et al. 2006). However, the mono-methylation at these residues represented the gene activation (Barski et al. 2007; Vakoc et al. 2006). These DNA modifications form the basis of epigenetics, which has taken on a prominent role in relating experience to psychiatric phenotypes (Klengel and Binder 2015).

## RNA Polymerases

There are three distinct classes of RNA polymerase—RNA polymerase I (Pol I), RNA polymerase II (Pol II), and RNA polymerase III (Pol III)—in the nucleus of eukaryotic cells, and they are designed to carry out transcription. RNA Pol I synthesizes large rRNA molecules. RNA Pol II is mainly

used to yield mRNA and, subsequently, proteins. RNA Pol III produces small RNA, including rRNA and tRNA molecules. Each class of RNA polymerase recognizes particular types of genes. However, RNA polymerases do not bind to DNA directly. Rather, they are recruited to DNA by other proteins that bind to promoters (Figure 1-2).

**FIGURE 1-2.** Transcription factors and RNA polymerase II (Pol II) complex.

Typical transcription factors contain DNA binding domains, dimerization domains, and transcription activation domains. Some transcription factors (e.g., cAMP response element-binding protein [CREB]) may be modified by phosphorylation. The transcription activation domain interacts with an RNA Pol II complex to induce transcription. TATA binding protein (TBP) binds to the TATA box element and associates with general transcription factors (TFII). This gene transcription apparatus recruits Pol II to the appropriate gene.

mRNA is transcribed from DNA by RNA Pol II, with heterogeneous nuclear RNA (hnRNA), an intermediate product. The core promoter recognized by Pol II is the TATA box (Hogness box), a sequence rich in nucleotides A and T, which is usually located 25–30 bases upstream of the transcription start site. The TATA box determines the start site of transcription and orients the basal transcription

complex that binds to DNA and recruits RNA Pol II to the TATA box; thus, it establishes the 5' to 3' direction in which Pol II synthesizes RNA. The formation of the basal transcription complex is promoted by a TATA box binding protein (TBP) that binds core promoter together with multiple TBP-associated factors and other general transcription factors. *Enhancers* are DNA sequences that increase the rate of initiation of transcription by RNA Pol II through its interaction with transcription factors, which can be located “upstream” or “downstream” of the transcription start site. Enhancer elements are important to cell-specific and stimulus-dependent expression of hnRNA. Some Pol II species, including those for many genes that are expressed in neurons, lack a TATA box and possess instead an *initiator*, a poorly conserved genetic promoter element.

## Transcription Factors

Transcription factors act as the key regulators of gene expression. Sequence-specific transcription factors typically contain physically distinct functional domains (see [Figure 1-2](#)). Numerous transcription factors have been found. Some of them translocate to the nucleus to bind their *cis*-regulatory elements in response to their activation reaction, such as nuclear factor  $\kappa$ B (NF- $\kappa$ B). However, some transcription factors are already bound to their cognate *cis*-regulatory elements in the nucleus under basal conditions and are converted into transcriptional activators by phosphorylation. cAMP (cyclic 3'-5'-adenosine monophosphate) response element-binding protein (CREB), for example, is bound to regions of DNA, called *cAMP response elements* (CREs), before cell stimulation.

CREB can promote transcription when it is phosphorylated on a serine residue (ser133), because phosphorylated CREB can interact with a coactivator, CREB-binding protein (CBP), which in turn contacts and activates the basal transcription complex. Of interest, CBP possesses intrinsic histone acetyltransferase activity. The activity of most transcription factors is regulated through second-messenger pathways. CREB can be activated via phosphorylation at ser133 by second messengers such as cAMP,  $\text{Ca}^{++}$ , and growth factors (Kandel 2012) (Figure 1-3).

**FIGURE 1-3.** Activation of cAMP response element-binding protein (CREB) via different signal

## transduction pathways.

Signal cascades are activated by external stimuli, such as hormones or neurotransmitters and growth factors. *Arrows* indicate the interaction between pathways. AC=adenylyl cyclase; C=catalytic subunits of PKA;  $Ca^{++}$ =calcium; CaMK IV=calmodulin-dependent kinase IV; cAMP=cyclic 3'-5'-adenosine monophosphate; CBP=CREB-binding protein; Epac=exchange protein activated by cAMP; ERK=extracellular-regulated kinase;  $G\alpha_s$ = $\alpha$  subunit of the stimulatory G protein; P=phosphorylation; PKA=cAMP-dependent protein kinase; R=regulatory subunits of PKA; Rap and Ras=small GTPases (small proteins that bind to guanosine triphosphate [GTP]); RSK2=ribosomal S6 kinase 2.

CREB is a molecule that is widely implicated in learning and memory in many species. Mice expressing mutant CREB isoforms show impaired memory, but this is dependent on the genetic background of the mice ([Graves et al. 2002](#)). CBP is a transcriptional coactivator with CREB. A partial-knockout mouse model, in which CBP activity is lost, exhibits learning deficiencies ([Oike et al. 1999](#)). Furthermore, Rubinstein-Taybi syndrome (RTS) is an autosomal-dominant dysmorphic syndrome that results in severe impairment of learning and memory. The RTS gene has been mapped to chromosome 16 and identified as CBP. Loss of the function of CBP is likely one important contributing factor to the learning and memory defects seen in RTS ([Murata et al. 2001](#); [Oike et al. 1999](#); [Petrij et al. 1995](#)).

## Posttranscriptional Modification of RNA

The mRNA of prokaryotes can be used without any modification to direct protein synthesis, but posttranscriptional processing of mRNA is required in eukaryotes. The DNA sequences that code for mRNA (exons) are frequently interrupted by intervening DNA sequences (introns). When a protein-coding gene is first transcribed, the hnRNA contains both exons and introns. Before the transcript exits the nucleus, its introns are removed and its exons are spliced to form mature mRNA (Figure 1-4.) The hnRNA that is synthesized by RNA polymerase has a 7-methyl-guanosine “cap” added at the 5’ end. The cap appears to facilitate the initiation of translation and to help stabilize the mRNA. In addition, most eukaryotic mRNA has a chain of 40-200 adenine nucleotides attached to the 3’ end of mRNA. The poly (A) tail is not transcribed from DNA; rather, it is added after transcription by the nuclear enzyme poly (A) polymerase. The poly (A) tail may help stabilize the mRNA and facilitate mRNA exit from the nucleus. After the mRNA enters the cytoplasm, the poly (A) tail is gradually shortened.

**FIGURE 1-4.** Transcription and RNA splicing.

The horizontal black line between exons indicates intron. The region before the first exon is the 5' regulatory region of the gene, such as a TATA box. There also are *cis*-regulatory elements in introns and downstream of the last exon. The heterogeneous nuclear RNA (hnRNA), containing both exons and introns, is spliced to form mRNA. mRNAs are then exported from the nucleus to the cytoplasm, where they will direct the synthesis of distinct proteins.

## RNA Editing

RNA editing has been observed in eukaryotes ranging from protozoa to mammals and is now recognized as a type of RNA process (posttranscriptional modification of RNA) that differs from the well-known processes of RNA splicing, 5' end formation, and 3' endonucleolytic cleavage and polyadenylation ([DeCerbo and Carmichael 2005](#); [Kable et al. 1997](#)). The conversion of adenosine to inosine was observed first in yeast tRNA ([Grosjean et al. 1996](#)) but has since been detected in viral RNA transcripts and mammalian cellular RNA ([Bass 1997](#); [Simpson and Emeson 1996](#)). The inosine residues generated from adenosines can alter the coding information of the transcripts, as inosine is synonymous for guanosine during transcript translation. For example, upon A-to-I editing the CAC codon for histamine is transformed to CIC, coding for arginine. RNA editing can have dramatic consequences for the expression of genetic information, and in a number of cases it has been shown to lead to the expression of proteins not only with altered amino acid sequences from those predicted from the DNA sequence but also with altered biological functions ([Bass 2002](#); [Burns et al. 1997](#)).

The enzymes for RNA editing are referred to as *adenosine deaminases that act on RNA* (ADARs). ADARs target double-stranded RNA (dsRNA) and convert adenosines to inosines by catalyzing a hydrolytic deamination at the adenine base ([Bass 2002](#)). Mammals have several ADARs, of which two, ADAR1 and ADAR2, are expressed in most tissues of the body ([Seeburg and Hartner 2003](#)). RNA editing may also catalyze the conversion of a small number of adenosines in a transcript to inosines ([Stuart and Panigrahi 2002](#)). On the other hand, RNA editing can convert numerous adenosines to inosines in RNA. This type of editing is thought to be the result of aberrant production of dsRNA ([DeCerbo and Carmichael 2005](#)) and has been suggested to lead to RNA degradation ([Scadden and Smith 2001](#)), nuclear retention ([Zhang and Carmichael 2001](#)), or even gene silencing ([Wang et al. 2005](#)).

The serotonin 5-HT<sub>2C</sub> receptor is a G protein-coupled receptor that has variants generated by A-to-I editing ([Burns et al. 1997](#)). 5-HT<sub>2C</sub> receptor transcripts can be edited at up to five sites, potentially generating 24 different receptor versions and hence a diverse receptor population. The RNA-edited 5-HT<sub>2C</sub> receptor affects ligand affinity and the efficacy of G protein coupling ([Berg et al. 2001](#); [Wang et al. 2000](#); [Yang et al. 2004](#)). The unedited form of the 5-HT<sub>2C</sub> receptor has the highest affinity to serotonin and exhibits constitutive activity independent of serotonin or serotonergic agonists. When RNA is edited, the basal activity of the 5-HT<sub>2C</sub> receptor is suppressed, and agonist potency and efficacy are modified.

# Non-Coding RNAs

About 2% of the human genome is transcribed into mature protein-coding RNAs, whereas the large majority, 70%–90%, is transcribed into non-protein-coding RNAs (ncRNAs). Classes of noncoding transcripts can be divided between housekeeping noncoding RNAs and regulatory noncoding RNAs. Housekeeping ncRNAs include rRNA, tRNA, snRNA, and small nucleolar RNAs and are usually expressed constitutively. Regulatory ncRNAs can be classified into miRNAs, Piwi-interacting RNAs (piRNAs), small interfering RNAs (siRNAs), promoter and enhancer RNAs, and long noncoding RNAs (lncRNAs) ([Kaikkonen et al. 2011](#); [Ponting et al. 2009](#)). The majority of the non-protein-coding transcripts belong to the group of lncRNAs, which are arbitrarily considered as >200 nucleotides in length ([Ponting et al. 2009](#)). However, many of these lncRNAs can also act as primary transcripts for the production of short RNAs, making the categorization of this group of ncRNAs ambiguous ([Kaikkonen et al. 2011](#)). The best-known ncRNAs are endogenous siRNAs. SiRNAs, together with miRNAs and piRNAs, play an instrumental regulatory and defensive role in organisms. These three classes of small RNAs show overlap with regard to their structure, synthesis, and biological role. Endogenous siRNAs are involved in gene regulation and transposon silencing, although the latter mechanism is still not understood.

## Modification of the Nascent Polypeptide Chain

Posttranslational modifications occur after translation is initiated. They may include removal of part of the translated sequence or the covalent addition of one or more chemical groups that are required for protein activity. Some of these modifications, such as glycosylation or prenylation, represent an obligatory step in the synthesis of the “finished” protein product. In addition, many proteins may be activated or inactivated by covalent attachment of a variety of chemical groups. Phosphorylation, glycosylation, hydroxylation, and prenylation are common types of covalent alterations in posttranslational modifications. A number of different enzymes coordinate these processes, and they represent a major portion of the events of cellular signaling.

## **Experimental Approaches to Determining and Manipulating Gene Expression**

---

Changes in gene expression within the central nervous system (CNS) have profound effects for all other aspects of the organism. Changes in gene expression are causally associated not only with the development of the CNS but also with the complex phenomena of brain function, such as memory formation, learning, cognition, and affective state. Changes in gene expression likely underlie the pathogenesis of many sporadic or inherited CNS-related disorders, such as Alzheimer’s disease, Huntington’s disease, depression, and schizophrenia. Thus, insight into and characterization of gene expression profiles are

necessary steps for understanding how the brain functions at the molecular level and how malfunction will result in disease. Molecular biological and genomic technologies such as gene mapping and cloning, DNA libraries, gene transfection and expression, and gene knockout and gene targeting have provided numerous benefits to neuropsychopharmacology. Genomic methods applied to pedigree and population samples of patients with psychiatric disorders may soon make it possible to identify genes contributing to the etiology and pathogenesis of these diseases and to provide a potential basis for new therapies.

## Cloning of DNA

The cloning of DNA confers the ability to replicate and amplify individual pieces of genes. Cloning can be performed with genomic DNA or complementary DNA (cDNA). cDNA is synthesized artificially from mRNA in vitro with the aid of *reverse transcriptase*. Cloned genomic DNA may contain any stretch of DNA, either intron or exon, whereas cloned cDNA consists only of exons. For cloning ([Figure 1-5](#) outlines the process), the desired pieces of DNA (often called “inserts”) are connected with the DNA of genetically engineered vectors or plasmids and then introduced into hosts such as bacteria or mammalian cells. A DNA library is a collection of cloned restriction fragments of the DNA of an organism that consists of random pieces of genomic DNA (i.e., genomic library) or cDNA (i.e., cDNA library). Complete cDNA libraries contain all of the mRNA molecules expressed in a certain tissue. Sometimes cDNA libraries can be from a specific tissue in a distinct

circumstance. For example, a cDNA library could be made from cerebral cortex in rats with transient forebrain ischemia ([Abe et al. 1993](#)).

**FIGURE 1-5.** Outline of gene cloning.

See text for details.

The cloning of disease-related genes is an important step toward insight into the pathogenesis of diseases and development of new drugs against these diseases. If a

protein is suspected of involvement in pathogenesis, a nucleic acid sequence can be deduced from the partial amino acid sequence. cDNA libraries are screened with the partial sequence in order to fish out a complete clone of interest. The isolated cDNA molecules are used to infect bacteria, which amplify the cloned cDNA. Bacteria expressing these cDNA molecules will often make the protein of interest, which can be detected with antibody. A variation on the above technique uses antibodies against the purified proteins to screen a DNA library transfected into bacteriophages. The bacteriophages containing the “right” cDNA can be retrieved, and the sequence of cDNA can be analyzed.

## **Polymerase Chain Reaction**

*Polymerase chain reaction* (PCR) is a rapid procedure for in vitro enzymatic amplification of specific segments of DNA. Amplification of the genes of interest occurs by selecting and synthesizing “primers”—stretches of DNA that span the region of interest to be “filled in”—and heating DNA to make it single stranded, allowing polymerase and primers to bind. The polymerase then reads the “blank” stretch of DNA between the primers and synthesizes DNA corresponding to the region of interest. This is usually done in thermal cyclers that heat the DNA at regular intervals and allow “cycles” of PCR to amplify the genes repetitively. To avoid continual addition of polymerase, the DNA polymerase used is often from bacteria that inhabit hot springs or hot ocean vents. This polymerase is not denatured by heating and can support several cycles of PCR.

A variation on PCR is reverse transcriptase PCR (RT-PCR), in which the RNA is the template. Reverse transcriptase is

employed to synthesize cDNA from the RNA. Enzymatic amplification of this cDNA is then accomplished using PCR.

Real-time PCR is based on the method of RT-PCR, following the reverse transcription of RNA into cDNA. Real-time PCR requires suitable detection chemistries to report the presence of PCR products, as well as an instrument to monitor the amplification in real time. Generally, chemistries in PCR consist of fluorescent probes. Several probes exist, including DNA binding dyes such as ethidium bromide (EtBr) or SYBR green I, hydrolysis probes (5'-nuclease probes), and hybridization probes ([Valasek and Repa 2005](#)). Each type of probe has its own unique characteristics, but the strategy for each is to link a change in fluorescence to amplification of DNA ([Kubista et al. 2006](#)). The instrumentation to detect the production of PCR must be able to input energy for excitation of fluorescent chemistries at the desired wavelength and simultaneously detect a particular emission wavelength. Many instrument platforms are available for real-time PCR. The major differences among them are the excitation and emission wavelengths that are available, speed, and the number of reactions that can be run in parallel ([Kubista et al. 2006](#)).

## Positional Cloning

Disease genes can sometimes be isolated with the aid of *positional cloning*, a process also known as *reverse genetics* ([Collins 1995](#)). Positional cloning is the process used to identify a disease gene based only on knowledge of its chromosomal location, without any knowledge of the gene's biological function. Positional cloning requires a genetic map of unique DNA segments or genes (genetic markers), with known chromosomal locations, that exist in several alternative forms (alleles). These allelic variations

(polymorphisms) allow comparisons of the wild type as the “diseased” genotype.

Linkage analysis is a method of localizing one or more genes influencing a trait to specific chromosomal regions. This is performed by examining the cosegregation of the phenotype of interest with genetic markers. Relatives who are phenotypically alike will share common alleles at markers surrounding the genes influencing the phenotype, whereas relatives who are phenotypically dissimilar will not share these alleles. To carry out linkage analyses, investigators need, minimally, a set of families in which phenotypic individuals have known relationships to one another and the genotypes of these individuals, including one or more genetic markers.

Once the chromosomal location of the disease gene has been ascertained, the area of chromosomal DNA can be cloned. Until recently, the process of positional cloning involved laborious efforts to build a physical map and to sequence the region. (The sequencing of the human genome has obviated this step). Physical maps can be produced by isolating and linking together yeast and/or bacterial artificial chromosomes containing segments of human DNA from the region. These fragments are then sequenced and ordered, and from these data, the genomic DNA sequence for the region of the candidate gene is determined.

## Differential Display

The technique of differential display is designed to determine the complement of genes being expressed (mRNAs) by a tissue or organ at a given point in time. The

establishment of differential display is dependent on the random amplification and subsequent size separation of cDNA molecules ([Liang et al. 1992](#)). With RT-PCR amplification with specific oligo-T primers (one- or two-base anchored oligo-dT primers, such as oligo-T-XC, oligo-T-XG, oligo-T-XT, and oligo-T-XA; X=G/A/C), four separate cDNA synthesis reactions are performed. These cDNA synthesis reactions form the four pools of cDNA for one original mRNA population. The resulting cDNA molecules from each RT-PCR reaction are amplified, using the same primer of the reverse transcription step plus randomly chosen primers. Because the randomly chosen primers will anneal at various locations upstream of the oligo-T site, many individual cDNA fragments of different sizes are amplified in each PCR reaction. cDNA fragments derived from different original mRNA populations are sized and then separated on parallel gels to analyze the presence of unique bands. The differentially expressed cDNA fragments can be excised from gels, cloned, and further characterized by a variety of technologies based on different purposes, such as in situ hybridization, sequences, and Northern blot analysis.

Differential display is a useful tool for identifying region-specific mRNA transcripts in brain. The molecular markers for these regions can be found by screening for gene expression in specific brain regions or nuclei ([Mizushima et al. 2000](#); [Tochitani et al. 2001](#)). In addition, under different stimulation or behavioral conditions, the changes in gene expression can be explored by differential display ([Hong et al. 2002](#); [Liu et al. 2002](#); [Mello et al. 1997](#); [Tsai et al. 2002](#)). This technique has even been adapted to indicate the RNA expression profile of an individual neuron ([Eberwine et al. 1992](#)). Many genes related to ischemia or Alzheimer's disease in CNS have also been isolated using differential

display ([Doyu et al. 2001](#); [Imaizumi et al. 1997](#); [Tanaka et al. 2002](#)). Genes that are activated in response to chronic drug treatment (e.g., with opiates or antidepressants) can also be identified this way. Furthermore, as described later in this chapter, streamlined technologies are now available for this purpose.

## Gene Delivery Into Mammalian Cells

The introduction of recombinant DNA (including desired genes) into cells is an important strategy for understanding certain gene functions in neurons or glia. Gene function studies have benefited diagnosis and therapy for a variety of disorders that affect the CNS. The delivery of desired genes into cells or brain regions provides the technological base for insight into molecular mechanisms of brain function and, ultimately, for gene therapy in the CNS.

### Vectors and Delivery

For gene transfer, it is necessary to incorporate the desired cDNA into various vectors, such as appropriate plasmids or replication-deficient viruses. Vectors used for transfection generally possess two essentially independent functions: 1) carrying genes to the target cell and 2) expressing the genes properly in the target cell. There are currently many commercial mechanisms with different features from which to choose; the choice is dependent on the purpose of the experiments and on the characterizations of exogenous desired genes. In one form of transfection, *stable transfection*, cells expressing the gene of interest can be actively selected by a marker (e.g., neomycin resistance genes, *Neo*), and the cDNA or other type of foreign DNA is

stably integrated into the DNA of a chromosome. In *transient transfection*, however, cells express the gene of interest for a few days. Cells for hosting the foreign DNA can be either established cell lines or primary cultured neuronal cells. The desired cDNA delivered into cells may be native genes, fragments of the genes, mutant genes, or chimeric genes.

The main barrier to the delivery of DNA into cells is getting the foreign DNA through the cellular membrane. Various methods have been developed to convey the foreign DNA molecules into mammalian cells. These include chemical or physical techniques, such as calcium phosphate coprecipitation of DNA, liposome fusion, electroporation, microinjection, ballistic injection, and viral infection. At present, methods dependent on incorporation of DNA into cationic liposomes are used most widely (e.g., lipofectin). These methods of transfection are accessible to both cell lines and cultured primary neuronal cells. The ratio of DNA to liposomal suspension, cell density, and time duration of exposure to the DNA-liposomal complex must be optimized for each cell type in culture.

## **Viral Vectors**

Several viral vectors with low toxicity, high infection rate, and persistent expression have extended the methodology of delivery of genes to mammalian cells. These viruses include DNA viruses, such as adenoviruses and adeno-associated viruses, herpes simplex viruses, and RNA retroviruses. As a result of advances in genetic manipulation, adenoviruses and adeno-associated viruses are now more widely applied to gene transfer. The advantages of the adenoviruses are 1) the ability to carry large sequences of foreign DNA, 2) the ability to infect a

broad range of cell types, and 3) an almost 100% expression of the foreign genes in cells.

Human adenovirus is a large DNA virus (containing about 36 kilobase pairs) composed of early genes (from *E1* to *E4*) and later genes (from *L1* to *L5*). Wild-type adenovirus cannot be applied to gene transfer because it causes a lytic infection. Thus, recombinant adenoviruses with defects of some essential viral genes are used for gene delivery. These adenoviral expression systems are safe, have the capacity for large DNA inserts, and allow for relatively simple adenoviral production ([Harding et al. 1997](#); [He et al. 1998](#)).

The process of gene transfer into cells (cell lines and primary cells) via recombinant adenoviruses is simple, but the optimal viral titer, the time of exposure to virus, and the multiplicity of infection should be optimized for each cell type. Cell lines and a variety of primary neuronal cells have been infected by adenoviruses ([Barkats et al. 1996](#); [Chen and Lambert 2000](#); [Hughes et al. 2002](#); [Koshimizu et al. 2002](#); [Slack et al. 1996](#)). In addition, recombinant adenoviruses containing the desired genes can be delivered to neurons in vivo via intracerebral injection into particular brain areas ([Bemelmans et al. 1999](#); [Benraiss et al. 2001](#); [Berry et al. 2001](#); [Neve 1993](#)).

## Identification of Ectopic Gene Expression

After delivery of the desired genes into cells, identification of their proper expression is necessary. The general strategies for identification ([Chalfie et al. 1994](#); [Czysz et al. 2015](#); [Kohara et al. 2001](#); [Yu and Rasenick 2002](#)) include the following:

1. The measurement of some functional changes elicited by gene expression in targeted cells. If an enzyme is

expressed, this would involve measuring the activity of that enzyme.

2. The detection of the proteins coded by the desired genes via techniques relying on antibodies, such as western blot, immunoprecipitation, and immunocytochemistry. Expression of the desired genes tagged with some epitopes, such as HA, GST, and His-tag, can also be determined using antibodies directed against these epitopes.
3. The use of green fluorescent protein (GFP) as an indicator. GFP, a protein from the jellyfish *Aequorea victoria*, can be either cotransfected with the desired genes or fused with the desired genes before incorporation into cells. The fluorescence from GFP is easy to detect using fluorescent microscopy, and this allows the monitoring of gene expression in living cells. Furthermore, if GFP is fused with the gene of interest, the fluorescence from GFP provides a useful tool for studying the function and cellular localization of proteins coded by the genes of interest.

Several different “colors” have been developed through mutation of the initial GFP gene. Depending on the wavelengths of excitation, they can be used to localize multiple protein species, or fluorescence resonance energy transfer (FRET) can be used to demonstrate that two target proteins are in close (<10 nm) proximity. FRET uses two fluors with little spectral overlap and depends on the emission of one of the fluors exciting the other.

# Inhibition of Cellular Gene Expression

---

## RNA Interference

RNA interference (RNAi) is believed to be a biologically conserved function in a wide range of eukaryotic species. It may play a role in protection against dsRNA viruses ([Sijen et al. 2001](#)) and genome-invading transposable elements ([Provost et al. 2002](#); [Volpe et al. 2002](#)). Triggered by dsRNA, RNAi identifies and destroys the mRNA that shares homology with the dsRNA. Thus, the expression of a particular gene can be suppressed by introducing dsRNA whose antisense strand sequence matches the mRNA sequence. miRNA and siRNA are central to RNA interference.

[Fire et al. \(1998\)](#) first described RNAi in the nematode *Caenorhabditis elegans* as sequence-specific gene silencing in response to dsRNA. The mechanism of RNAi is partly understood, and key proteins involved in the pathway have been identified. In brief, the process of siRNA involves a series of steps. In a first initiation step, Dicer, an enzyme of the RNase III family, initiates ATP-dependent fragmentation of long dsRNA into 21- to 25-nucleotide double-stranded fragments, termed *small interfering RNAs* (siRNAs). These siRNAs are specifically characterized by overhanging 3' ends of two nucleotides and phosphorylated 5' ends. The siRNA duplexes bind with Dicer, which facilitates the formation of an siRNA/multiprotein complex called *RISC loading complex* (RLC). The siRNA duplex in RLC then unwinds (which requires the protein Ago2) to form an

active *RNA-induced silencing complex* (RISC) that contains a single-stranded RNA (called the *guide strand*). The RISC recognizes the target RNA through Watson-Crick base pairing with the guide strand and cleaves the target RNA. Finally, the RISC releases its cleaved product and goes on to catalyze a new cycle of target recognition and cleavage (Figure 1-6) (Tomari and Zamore 2005; Xia et al. 2005).

**FIGURE 1-6.** A schematic of the mechanism of RNA interference (RNAi) posttranscriptional knockdown of a gene product.

The procedure starts with introduction (transfection, electroporation, or injection) of double-stranded RNA (dsRNA) or small interfering RNA (siRNA) into cells, or expression of small hairpin RNA (shRNA) in cells with vectors encoding shRNAs. The

cellular ribonuclease (RNase) Dicer recognizes the long dsRNA molecules and shRNA. Subsequently, the dsRNA is cleaved, resulting in 21-nt RNA duplexes, the siRNAs. These siRNA molecules are then incorporated into the RNA-induced silencing complex (RISC) multiprotein complex, where they are unwound by an adenosine triphosphate (ATP)-dependent process, transforming the complex into an active state. Activated RISC uses one strand of the RNA as a bait to bind homologous RNA molecules. The target RNA is cleaved and degraded, resulting in gene silencing. mRNA=messenger RNA; pol III=RNA polymerase III.

miRNAs are formed in a similar manner, from longer RNA precursors, and are processed in the cytoplasm by Dicer before becoming part of RISC. However, siRNAs are the products of exogenous dsRNAs that are taken up by cells or that enter via vectors such as viruses. siRNAs bind to mRNA in the case of complete complementarity. miRNAs are products of endogenous ncRNA encoded from genes of the genome. They do not require full complementarity to bind with target mRNA (e.g., one type of miRNA may regulate many genes, and one gene may be regulated by several miRNAs) ([Carthew and Sontheimer 2009](#)).

## RNAi Knockdown of Gene Expression

Knockdown of gene expression is accomplished by designing siRNA sequences that target the coding and noncoding regions of the specified mRNAs with perfect complementarity. In mammalian cells, administration of siRNAs is effective in short-term investigations. Introduction of siRNA into cells is accomplished by transfection or electroporation of either the specific siRNA itself or small hairpin RNA (shRNA), in which the hair loop

is rapidly cleaved to produce siRNA. Most of the proposed applications of RNAi incorporate 21-nt siRNA duplexes that have 2-nt 3' overhangs, which allow large-scale and uniform production of siRNA molecules that can be chemically stabilized. In some siRNA-target combinations, the use of longer dsRNAs can increase the potency of RNAi ([Kim et al. 2005](#); [Siolas et al. 2005](#)).

For stable longer-term suppression, a gene construct coding for the shRNA with a Pol III or a Pol II promoter can be applied ([Brummelkamp et al. 2002](#); [Shi 2003](#)). RNA Pol II and III promoters are used to drive expression of shRNA constructs ([Amarzguoui et al. 2005](#)), depending on the type of expression required. Pol III promoters drive high levels of constitutive shRNA expression, and their transcription initiation points and termination signals are well defined. Pol II promoter-driven shRNAs can be expressed tissue-specifically ([Zeng et al. 2002](#)). Expressed shRNAs are incorporated into RISC, leading to a more potent inhibition of target gene expression. Generally, viral vectors such as adenovirus, lentivirus, and adeno-associated virus can carry the gene construct into cells to achieve adequate and prolonged expression for knockdown ([Kim and Rossi 2007](#)).

## RNAi Applications

RNAi is a straightforward method for inducing sequence-specific silencing of one or more genes of interest with the introduction of siRNAs. It has been a powerful tool for investigating gene function. Studies using RNAi have been performed in neuronal cells to examine the functional roles of individual genes in developing growth cones and neurite

outgrowth ([Eriksson et al. 2007](#); [Hengst et al. 2006](#); [Liu et al. 2007](#); [Schmitz et al. 2007](#); [Yanaka et al. 2007](#)), ion channels ([Geng et al. 2004](#); [Lauver et al. 2006](#); [Tahiliani et al. 2007](#)), apoptosis ([Yano et al. 2007](#); [Zhang et al. 2007](#)), and a variety of signaling pathways ([Meuer et al. 2007](#); [Sanada and Tsai 2005](#); [Shi et al. 2006](#); [Yamada et al. 2005](#)). Furthermore, RNAi is now being used for the knockdown of gene expression in animals. It appears to apply in virtually all mammalian species, as exemplified by its capability for silencing genes in mice, rats, and goats ([Peng et al. 2006](#); [Zhou et al. 2007](#)). Inducible RNAi based on the Cre-loxP system has also been developed in transgenic mice, enabling the investigator to control gene silencing both spatially and temporally ([Chang et al. 2004](#); [Coumoul et al. 2005](#); [Xia et al. 2006](#)).

The success of RNAi knockdown of specific genes suggests the possibility of using RNAi for therapeutic gene disruption. For example, RNAi-based therapies for age-related macular degeneration and respiratory syncytial virus have reached clinical trials. At this point in time, however, a number of concerns about both safety and efficacy need to be addressed.

RNAi has become a frequently used tool in a wide range of biomedical research. It provides a convenient method to study gene function via application of RNAi to cell lines, cultures, and embryonic stem cells. New uses for this tool are expected to be discovered.

## Chromatin Immunoprecipitation

The purpose of chromatin immunoprecipitation (ChIP) is to identify genomic sequence(s) associated with a protein of

interest ([Solomon et al. 1988](#)). ChIP has become the technique of choice to determine the genomic enrichment profiles of transcription factors, posttranslationally modified histones, histone variants, or chromatin-modifying enzymes. The method comprises three basic steps: 1) covalent cross-links between proteins and DNA are formed, typically by treating cells with formaldehyde or another chemical reagent; 2) an antibody specific to the protein of interest is used to coimmunoprecipitate the protein-bound DNA fragments that were covalently cross-linked; and 3) the immunoprecipitated protein-DNA links are reversed. DNA sequences associated with the precipitated protein can be identified by dot or slot blot, PCR, quantitative PCR (qPCR), labeling and hybridization to genomewide or tiling DNA microarrays (ChIP-Chip technique) ([Lee et al. 2006](#)), and sequencing technology ([Gogol-Döring and Chen 2012](#)).

---

## Genome-Editing Technologies

---

Genome-editing technologies based on site-specific DNA nucleases allow introduction of genetic modifications into almost any cell type and organism. To date, four major classes of customizable DNA binding proteins have been engineered for this purpose: meganucleases derived from microbial mobile genetic elements ([Smith et al. 2006](#)), zinc finger nucleases based on eukaryotic transcription factors ([Miller et al. 2007](#); [Urnov et al. 2005](#)), transcription activator-like effectors from *Xanthomonas* bacteria ([Christian et al. 2010](#); [Miller et al. 2011](#)), and the RNA-guided DNA endonuclease Cas9 (CRISPR-associated protein 9) from the type II bacterial adaptive immune

system CRISPR (clustered regularly interspaced short palindromic repeats) ([Cong et al. 2013](#); [Mali et al. 2013](#)). The most rapidly developing is the CRISPR/Cas9 system, which can be targeted to virtually any genomic location of choice via a short RNA guide. The CRISPR locus is typically composed of a clustered set of CRISPR-associated (Cas) genes and a series of repeat sequences interspaced by variable sequences (spacers) corresponding to sequences within foreign genetic elements (protospacers). A long pre-crRNA transcribed from the spacer-repeat CRISPR locus is processed into shorter CRISPR RNAs (crRNAs), which direct the nucleolytic activity of certain Cas enzymes to degrade target nucleic acids ([Brouns et al. 2008](#); [Hale et al. 2009](#)).

Prokaryotes have evolved diverse RNA-mediated systems that use short crRNAs and Cas proteins to detect and defend against viral DNA elements ([Bhaya et al. 2011](#); [Marraffini and Sontheimer 2008, 2010](#); [Wiedenheft et al. 2012](#)). The guide sequence within these crRNAs can be easily replaced by a sequence of interest to retarget the Cas9 nuclease. A simple two-component system—consisting of Cas9 from the bacterial species *Streptococcus pyogenes* ([Cong et al. 2013](#); [Mali et al. 2013](#)) or *Staphylococcus aureus* ([Ran et al. 2015](#)) and a fusion of the trans-activating crRNA-crRNA duplex to a single-guide RNA (sgRNA) ([Jinek et al. 2012](#))—has been engineered for expression in eukaryotic cells and can achieve DNA cleavage at any genomic locus of interest. Hence, Cas proteins can be targeted to specific DNA sequences simply by changing the short specificity-determining part of the guide RNA (gRNA), which can be easily achieved in one cloning step ([Heidenreich and Zhang 2016](#)).

Three variants of the Cas9 nuclease have been adopted to help genome editing. The first is wild-type Cas9, which can cleave double-stranded DNA at specific sites to form double-stranded breaks (DSBs). DSBs can be repaired by the cellular non-homologous end joining (NHEJ) or homology-directed recombination (HDR) pathway ([Burma et al. 2006](#); [Kass et al. 2013](#); [Maruyama et al. 2015](#)). If a donor template with homology to the targeted locus is supplied, the DSB may be repaired by HDR. If an exogenous homology repair template is absent, the DSBs can be repaired by inducing insertion or deletion mutations (indels) via the NHEJ repair pathway ([Bibikova et al. 2002](#)). The second variant of the Cas9 nuclease is a mutant form, known as Cas9D10A ([Cong et al. 2013](#)). It cleaves only one DNA strand and does not activate NHEJ. Instead, in the presence of a homologous repair template, DNA repairs are conducted via the HDR pathway only, resulting in reduced indel mutations ([Cong et al. 2013](#); [Jinek et al. 2012](#); [Qi et al. 2013](#)). The third variant is a nuclease-deficient Cas9 ([Qi et al. 2013](#)). Mutations inactivate cleavage activity but do not prevent DNA binding ([Gasiunas et al. 2012](#); [Jinek et al. 2012](#)). Therefore, this variant can be used either as a gene silencing or activation tool that “surgically” targets the desired region of the genome ([Gilbert et al. 2013](#); [Hu et al. 2014](#); [Maeder et al. 2013](#); [Perez-Pinera et al. 2013](#)). It can also be applied to visualize repetitive DNA sequences with a single sgRNA or nonrepetitive locus using multiple sgRNAs fused to enhanced green fluorescent protein ([Chen et al. 2013](#)). Alterations of gene sequence or expression induced by the CRISPR/Cas9 system are displayed in [Figure 1-7](#).

The CRISPR/Cas9 system has achieved widespread use in targeting genes in many cell lines and organisms, including humans ([Mali et al. 2013](#)), bacteria ([Fabre et al. 2014](#)), zebrafish ([Gonzales and Yeh 2014](#)), *Caenorhabditis elegans* ([Hai et al. 2014](#)), plants ([Mali et al. 2013](#)), frogs ([Bhattacharya et al. 2015](#)), yeast ([Jacobs et al. 2014](#)), flies ([Li and Scott 2015](#)), monkeys ([Chen et al. 2015](#)), rabbits ([Yan et al. 2014](#)), pigs ([Hai et al. 2014](#)), rats ([Bao et al. 2015](#)), and mice ([Kalebic et al. 2016](#)). In neuroscience research, the benefits of using CRISPR/Cas9 systems to study the nervous system are highlighted by several successful applications studying synaptic and circuit function, neuronal development, and diseases ([Heidenreich](#)

and Zhang 2016). The delivery of Cas9 and sgRNA to target the methyl CpG binding protein 2 gene *Mecp2* in the adult mouse brain demonstrated phenotypes observed in classic *Mecp2*-mutant mouse models and patients with Rett syndrome (Swiech et al. 2015). Cas9-mediated deletion of common tumor-suppressor genes in the cerebellum and forebrain efficiently induced the formation of medulloblastoma and glioblastoma tumors, respectively (Zuckermann et al. 2015). Although NHEJ in postmitotic neurons has been demonstrated to be active, introduction of precise genetic mutations via HDR in the brain may remain challenging. It is commonly believed that HDR predominantly occurs in the S (synthesis) and G<sub>2</sub> (gap between DNA synthesis and mitosis) phases of the cell cycle, and HDR is therefore thought to be rare in nondividing cells, such as neurons (Heidenreich and Zhang 2016).

Not all manipulations of gene products are made at the gene level. It is possible to modify cell function by interfering directly with gene products. One mechanism for such manipulation involves adding peptides that correspond to the active regions of proteins. These peptides bind to the molecular targets of those proteins within the cell and block the downstream effects. Sometimes these peptides can mimic the effect of the larger peptide. For example, a peptide corresponding to the carboxyl-terminal region of a G protein (which interacts with G protein-coupled receptors) was used to block the interaction between receptors and G proteins while “mimicking” the G protein to shift the receptor into a “high-affinity” agonist-binding state (Rasenick et al. 1994). Although this strategy usually involves adding peptides to cells made permeable with a detergent or with electric current, it is also possible

to incorporate DNA plasmids encoding peptides into cells ([Gilchrist et al. 1999](#)).

Another proteomic strategy for manipulating cellular processes involves expression of “dominant-negative” proteins that are generated in a sufficient amount to block the activity of the native protein in the cell. This strategy usually involves the construction of a mutant protein that is similar to the protein of interest but deficient at some active site. This inactive mutant protein, expressed in considerable excess over the native protein, competes with the native protein for target sites and inhibits its activity ([Osawa and Johnson 1991](#)).

## **Transgenic and Gene-Targeting Techniques**

---

Over the past few decades, progress in the development of molecular genetic methods has enabled the manipulation of genes in intact organisms, such as mice. The technologies have provided a powerful and useful tool that allows the study of gene function and promotes understanding of the molecular mechanisms of disorders of the brain and mind. The mouse genome is by far the most accessible mammalian genome for manipulation. Many successful procedures for introducing new genes, expressing elevated levels of genes, and eliminating or altering the function of identified target genes have been reported. Many mouse models produced by manipulating genes may be used in a variety of fields relevant to neuroscience. It is noteworthy, however, that behavioral studies in mice differ from those in rats, let alone primates, and several factors induce

variability. As a result, interpretation of genetically induced behavioral alterations must be interpreted with caution ([Richter et al. 2009](#)).

Generally, transgenic mice are those expressing exogenous DNA because of the insertion of a gene into the mouse genome. Usually, that gene is randomly located within the mouse genome, often as several copies. The use of transgenic mice has represented a major strategy for the investigation of genetic questions since the feasibility and reproducibility of stably introducing DNA by microinjection into individual male mouse embryos were established ([Markert 1983](#)). In DNA constructs used for the generation of transgenic mice, the gene of interest is located 3' to promoter sequences to produce a desired distribution of gene expression. The selection of the promoter is the most important consideration in generating transgenic mice. Some promoters, such as platelet-derived growth factor (PDGF), thy1 (a cell surface glycosylphosphatidylinositol-linked glycoprotein), prin (PrP), neuron-specific enolase (NSE), and glial fibrillary acidic protein (GFAP), have demonstrated the ability to direct high-level expression of exogenous genes in brain and/or in the neurons of mice ([Hsiao et al. 1996](#); [Nolte et al. 2001](#); [Sturchler-Pierrat et al. 1997](#); [Yang et al. 2004](#); [Zhu et al. 2001](#)). This level of expression can be modified by incorporation of a "tet-on" or "tet-off" vector into the desired inserted gene. Depending on the nature of the switch (on or off), the mouse will express the gene of interest when ingesting (or taken off) doxycycline.

"Gene targeting" refers to the homologous recombination that occurs between a specifically designed targeting construct and the chromosomal target of interest, in which recombination at the target locus leads to replacement of

the native target sequence with a construct sequence. The method enables the precise introduction of a mutant into one of many murine genes and has proven invaluable in examining the roles of gene functions in complex biological processes. Most of the target constructs are used to disrupt a target and to eliminate gene function (conventional “knockout”). Generally, a gene-targeting construct that contains positive-negative selection markers is prepared such that the target gene is interrupted by the gene for neomycin resistance, which also serves as a positive selection marker, and a thymidine kinase (TK) gene is adjacent to either one or both ends of the homologous genomic sequence for negative selection ([Gusella et al. 1983](#)). The positive-negative deletion scheme is employed to enrich for homologous recombination.

The targeting construct is often introduced into mouse embryonic stem (ES) cells by electroporation. Cells that fail to integrate the targeting construct into the genome are killed by application of neomycin in the culture medium (positive selection). The majority of the remaining cells, in which the entire construct (including the TK gene) inserts randomly, will die as a result of the incorporation of ganciclovir or fialuridine (inactive thymidine analogs), either of which blocks DNA synthesis. Homologous recombinant clones that do not contain the TK gene are used to prepare chimeric mice. Cells from these clones are microinjected into the fluid-filled cavity of 3.5-day-old embryos at the blastocyst stage. The injected embryos are then surgically transferred into the uterus of pseudopregnant females. These animals will give birth to chimeric mice. Breeding can be used to generate mice that are heterozygous and homozygous for the mutation.

Homozygous mutants may express the gene of interest in any cell of the body (Figure 1-8).

**FIGURE 1-8.** Conventional gene disruption ("knockout").

**(A) Producing chimeric mice.** First, a mutant allele is produced by replacing the coding exons of the desired gene with a neomycin (neo) cassette and transferred into embryonic stem (ES) cells. Second, genetically altered ES cells are reintroduced into a developing blastocyst, where they contribute to the developing embryo. **(B) Breeding chimeric mice.** When the germ cells of the resulting chimeric mouse (chimera) are ES cell-derived (germ-line mutation), the heterozygotes ( $+/-$ ) can be produced by breeding. One-half of the offspring will be heterozygous. The heterozygous

animals may be bred to produce homozygous mice (-/-).

## Use of Mutant Mice in Studies of Brain Disease

Transgenic mice produced by this method are generally gain-of-function mutants, because the transgene is designed either to express a novel gene product or to disrupt a normal gene product by expressing a “dominant-negative” alternative. It is also possible to put a DNA fragment in the opposite direction and hence to produce transgenic mice expressing antisense RNA, which will reduce gene function ([Jouvenceau et al. 1999](#); [Katsuki et al. 1988](#)). Expression of mutant amyloid precursor protein (APP) or presenilin 1 (PS1) or mutant forms of tau in mice has generated many animal models that may be related to Alzheimer’s disease. These transgenic mice have facilitated studies of the pathogenesis, molecular mechanisms, and behavioral abnormalities of Alzheimer’s disease ([Bornemann and Staufenbiel 2000](#); [Janus et al. 2001](#)). Nevertheless, because the transgene integrates into the mouse genome randomly and often exists as several copies, the interpretation of studies with transgenic mice is difficult.

Experiments with knockout mice have provided novel insights into the functional roles of neuronal genes and, in some case, animal models relevant to brain disorders. The targeted mutants in a gene of interest, however, can sometimes lead to embryonic lethality in mice, thus obscuring the particular role of that gene in a target tissue or in the adult. Furthermore, in some instances, genes

related to the gene that was eliminated undergo increased expression in the knockout mice. In this case, the related gene compensates for the gene of interest and yields a phenotype that resembles the “normal” animal. This has been seen for the knockouts of the axonal microtubule-associated protein tau ([Takei et al. 2000](#)). In the remainder of this section, we use Huntington’s disease (HD) to exemplify the use of transgenic mice in the study of neurological and psychiatric disease.

HD is a genetic neurological disorder that is inherited in an autosomal dominant manner. The gradual atrophy of the striatum is its pathological hallmark. It occurs in 3–10 per 100,000 individuals in Western Europe and North America ([Gil and Rego 2008](#)). The first symptoms generally appear in middle age, and the disease is progressive and invariably fatal 15–20 years after its onset ([Ho et al. 2001](#)). HD is caused by an expansion of cytosine-adenine-guanine (CAG) repeats in exon 1 of the HD gene. The HD gene is located on the short arm of chromosome 4 (4p63) and encodes the protein huntingtin, composed of more than 3,100 amino acids with a polyglutamine tail, which is widely expressed throughout the body in both neuronal and non-neuronal cells.

The function of huntingtin has been revealed with different research approaches, especially those with transgenic mice. Engineered knockout mice that disrupt exon 4 or the promoter of mouse HD gene homology *hdh* showed embryonic lethality. A subsequent study using mutant human huntingtin to compensate for the absence of endogenous huntingtin rescued the embryonic lethality of mice homozygous for a targeted disruption of the *hdh* gene ([Zuccato et al. 2001](#)). These findings suggest that huntingtin has an essential role for normal embryonic

development. Another study indicated that huntingtin is also required throughout life, because adult knockout mice became sterile, developed a progressive motor phenotype, and had a short life span after the *hdh* gene was inactivated during adulthood ([Dragatsis et al. 2000](#)). Furthermore, in yeast artificial chromosome 18 (YAC18) transgenic mice (which express full-length human huntingtin containing a nonpathogenic number [18Q] of polyglutamine repeats), overexpression of wild-type huntingtin containing 12 glutamine residues conferred significant protection against apoptosis triggered by *N*-methyl-D-aspartate (NMDA) receptor-mediated excitotoxicity ([Leavitt et al. 2006](#)), suggesting that huntingtin may play a role in cellular apoptosis.

As mentioned, HD is a neurodegenerative disorder caused by uninterrupted CAG trinucleotide repeats located near the 5' end in exon 1. Consequently, mutant huntingtin bears a tract of consecutive glutamine residues in its NH<sub>2</sub>-terminal, 17 amino acids downstream of the initiator ([Gil and Rego 2008](#)). The length of glutamine residues in the NH<sub>2</sub>-terminal of mutant huntingtin is the primary and predominant determinant for severity of HD. To elucidate the mechanism of neurodegeneration in HD, multiple mouse models of HD have been established. These models vary in terms of the site of transgene incorporation, promoter used, gene expression levels, CAG repeat length, and background mouse strain used. These transgenic models have facilitated investigations into potential pathogenic mechanisms of HD ([Pouladi et al. 2013](#)). The following are mouse models commonly used in huntingtin research.

1. *Mice expressing exon-1 fragments of human huntingtin gene (HD) containing polyglutamine mutations (R6/1, R6/2, and R6/5).* This transgenic mouse carries exon 1 of the HD gene with 115–155 CAG repeats. The transgene protein contains the first 69 amino acids of huntingtin in addition to the number of residues encoded by the CAG repeat. Extensive neuropathological analysis has been performed on the brains in R6/2 mice. The mice display subtle motor and learning deficits at approximately 1 month and overt symptoms by 2 months, and they usually die at 3 or 4 months. The characteristic nuclear inclusions were first detected with antibodies against the *N*-terminal portion of huntingtin in R6/2 mice. R6/2 mice show measurable deficits in motor behavior that increase progressively until death. R6/2 mice are a model of HD to use for studying the severity of motor symptoms or the course of the disease. In R6/2 mice, many neurotransmitter receptors, such as NMDA, AMPA, group II metabotropic glutamate (mGluR2), dopamine D<sub>2</sub>, and  $\gamma$ -aminobutyric acid (GABA), display an abnormal response to their ligands ([Ali and Levine 2006](#); [Cepeda et al. 2004](#); [Dunah et al. 2002](#); [Starling et al. 2005](#)).
2. *Mice expressing the full-length human HD gene.* Yeast artificial chromosomes (YACs) were used to create a YAC transgenic mouse model of HD that expresses the full-length human HD gene. The transgenic mice express human transgenic huntingtin with 18, 46, 72, or 128 polyglutamine repeats. The YAC mice with 72 CAG repeats (YAC72 mice) develop a progressive motor phenotype, neuronal dysfunction, and selective striatal neurodegeneration similar to that seen in HD by 12 months of age. YAC mice with 128 CAG repeats (YAC128 mice) exhibit initial hyperactivity, followed by the onset of

a motor deficit and finally hypokinesia, which show phenotypic uniformity with low interanimal variability present. The motor deficit in the YAC128 mice is highly correlated with striatal neuronal loss, providing a structural correlate for the behavioral changes ([Hodgson et al. 1999](#); [Slow et al. 2003](#)). These lines of transgenic mice may be extremely useful for preclinical experimental therapeutics.

3. *Knock-in HD transgenic mice.* In knock-in mice, a mutated DNA sequence is exchanged for the endogenous sequence without any other disruption of the gene. To establish the line of knock-in HD mice, scientists replaced CAG repeats in the murine *hdh* gene with human mutant CAG repeats. Knock-in HD mice are characterized by a biphasic progression in behavioral anomalies, and the nuclear inclusions appear late and are preceded by nuclear staining for huntingtin, followed by the presence of microaggregates of the mutant protein in the nucleus and the neuropil ([Menalled and Chesselet 2002](#); [Menalled et al. 2003](#)). The knock-in mouse is considered to be an ideal genetic model of HD for evaluating the effectiveness of new therapies and to study the mechanisms involved in the neuropathology of HD.

These three mouse models illustrate the usefulness of manipulation of the mouse genome for the study of human neuropsychiatric disease.

## Tissue-Specific Gene Manipulation

A tissue-specific mechanism for gene targeting is the Cre-loxP system. Both the Cre (cyclization recombination) recombinase and loxP sequences are derived from the P1

bacteriophage, which uses this recombination system in its life cycle to maintain the phage genome as a unit copy plasmid in the lysogenic state. The Cre-loxP system enables the specific manipulation of DNA based on the direction and location of the two loxPs. As a member of the integrase superfamily of site-specific recombinases, the Cre recombinase does not require any host cofactors or accessory proteins to mediate loxP-specific recombination. In most cases, loxP sites are placed in the same chromosome in direct repeat positions so that the intervening DNA sequence can be deleted. The loxP sites can also be placed in different chromosomes to promote recombination between different chromosomes, or they can be placed in an inverted position in the same chromosome to create a switch to inactivate and activate genes of interest ([Bouabe and Okkenhaug 2013](#)).

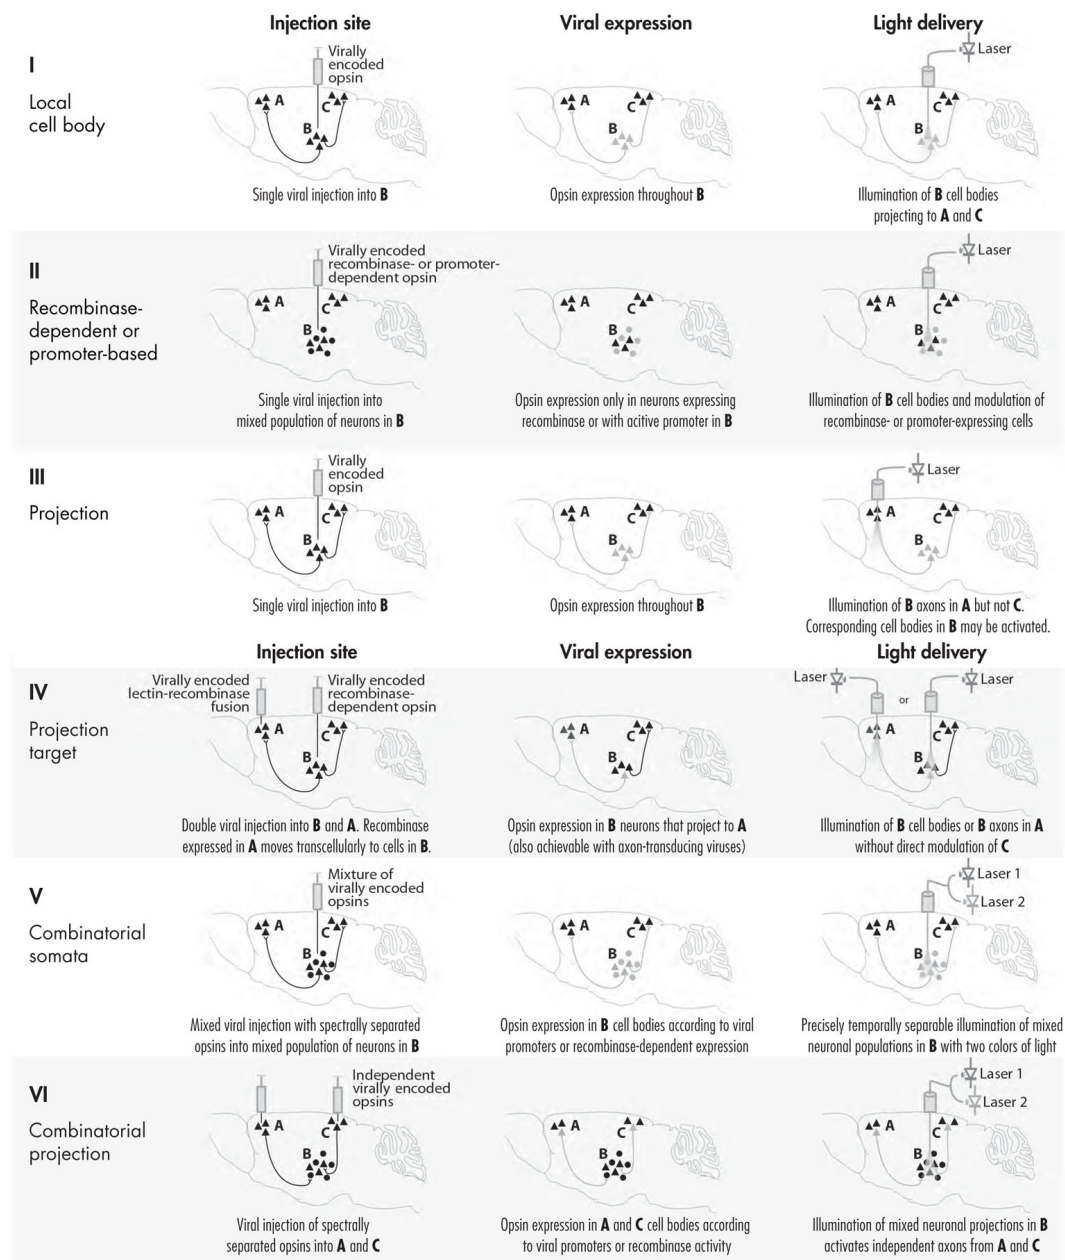

For conditional site-specific genome modification, two mouse lines are usually needed: 1) mice that have the DNA sequence of interest flanked by loxP sites (or “floxed”), which can be achieved by introducing loxP sites into the genomic locus of interest by homologous recombination as described in the previous paragraph, and 2) Cre recombinase transgenic mice, in which Cre is expressed under the control of a promoter that is active in specific cell types or tissues, or in which Cre is transiently expressed under the control of a promoter that is active at a particular developmental stage of tissues or cells. Cre expression can also be controlled temporally, by introducing an element into the promoter, which requires a ligand, such as a drug, for induction. When mice carrying such “floxed” genes are mated with transgenic mice expressing Cre recombinase, the target gene of the offspring is modified through Cre action in the cell types or tissues where Cre is expressed, or

in the cell or tissue when the mouse is treated with a drug, such as tamoxifen ([Bouabe and Okkenhaug 2013](#); [Friedel et al. 2011](#); [Liu et al. 2014](#)). Studies in which the NMDA receptor gene NR1 was deleted from specific hippocampal loci using Cre-loxP recombination technology reveal that a regional variation in NMDA receptor-dependent synaptic plasticity of postnatal excitatory neurons is required for specific aspects of hippocampal learning and memory ([McHugh et al. 2007](#); [Nakazawa et al. 2003](#)).

## Optogenetics

Optogenetics is a technique for parsing and manipulating specific neural circuits ([Figure 1-9](#)). Optogenetics was developed about 10 years ago and has been adapted both swiftly and broadly ([Deisseroth 2015](#)). Optogenetics makes use of microbial (bacterial and algal) opsins that have properties of both chromophores and ion channels. These molecules are unlike the metazoan rhodopsins, which convert light into an intracellular signal through a G protein-coupled receptor. Instead, these proteins (channelopsins and bacteriorhodopsin) form ion channels, and there are naturally occurring molecules that subserve both excitatory ( $\text{Na}^+$ ) and inhibitory ( $\text{Cl}^-$ ) functions, as activated by the channels.

**FIGURE 1-9.** Optogenetic manipulation of neural circuits.

*See **Plates 2 and 3** to view this figure in color.*

**(I)** Direct stimulation of neuronal cell bodies is achieved by injecting virus at the target region and then implanting a light-delivery device above the injected region. Even this simple experiment can provide specificity with viruses that will not

transduce afferent axons and fibers of passage. **(II)** Additional cell-type specificity is attained either by cell-type-specific promoters in the viral vector or via a recombinase-dependent virus, injected in a transgenic animal expressing a recombinase such as Cre in specific cells, leading to specific expression of the transgene only in defined cell types. **(III)** Projection (axonal) targeting is achieved by viral injection at the region harboring cell bodies, followed by implantation of a light-delivery device above the target region containing neuronal processes from the virally transduced region; in this way, cell types are targeted by virtue of their projections. **(IV)** Projection termination labeling is a more refined version of projection targeting, in which cells are targeted by virtue of synaptic connectivity to the target region, with likely exclusion of cells whose axons simply pass through the region. Transcellular labeling using a recombinase-dependent system is shown. Viruses expressing Cre fused to a transneuronal tracer (lectin) are delivered at the synaptic target site, and a Cre-dependent virus is injected into the region with cell bodies. Cells that project to the Cre-injected area express the Cre-dependent virus and become light sensitive. This can also be achieved with axon terminal-transducing viruses, although without control over the postsynaptic cell type. **(V)** Expression of two opsins with different characteristics in one brain region using a combination of promoter- or Cre-based approaches. Light delivery to the somata is performed using two different wavelengths designed to minimize cross-activation. **(VI)** Projections from two different brain regions are differentially stimulated with two wavelengths matched to the respective opsins expressed upstream.

The ingenious application that initially launched optogenetics toward worldwide adaptation was an engineered system that allowed both specificity of expression and specificity of excitation. This tool allowed an investigator to inject a virus encoding a channelrhodopsin activated by a specific wavelength of light and a targeting vector restricting expression to a certain class of cells (e.g., serotonergic) within a defined brain region. Introduction of a fiber-optic cable into the area of injection permitted the activation of the channelrhodopsin (and the subsequent activation or inhibition of the neuron containing that rhodopsin) by light. As the technique was further refined, channel opsins responsive to different wavelengths were expressed so that, depending on the wavelength used, different cells within a similar anatomic locus could be selectively activated or inhibited. The readout from such experiments could be anything from electrophysiological to behavioral. As optogenetics continues to be refined, the ability to translate from cells to circuits to behavior will increase in both complexity and resolution.

## **Proteomics and Beyond**

---

Shotgun proteomics takes its name from shotgun DNA sequencing, in which long DNA sequences are disassembled into shorter, easily readable components and reassembled. Shotgun proteomics works in much the same way, as the proteome of a cell is digested, subjected to analysis on mass spectrometry, and “reassembled” into proteins identified through a sophisticated bioinformatic analysis of the protein “fingerprint.” At first glance, such an approach

might seem problematic, because a tripeptide would have the same mass regardless of the order of the amino acids; however, ionization of the peptide reveals the order of the amino acids ([Filiou et al. 2011](#)).

Analysis if the proteome has the potential to yield much more information than simply the identity of the proteins being expressed in a given cell at a given time. Drugs that mimic, antagonize, or alter metabolism of neurotransmitters and neuromodulators make up the vast majority of the current psychiatric armamentarium. These drugs, often used chronically, have been shown to have long-term effects, altering second messenger systems. These second messengers (e.g., cAMP, inositol-1,4,5-triphosphate [IP<sub>3</sub>], cyclic guanosine monophosphate [cGMP]) activate or inhibit enzymes that modify proteins covalently. Phosphorylation, prenylation, and glycosylation are examples of these modifications, all of which can be determined in mass spectroscopic proteomic analysis.

In addition to—and in part due to—these modifications, molecules involved in neurotransmitter response and responsiveness move among cellular compartments in response to neurotransmitters, neuromodulators, and drugs that affect these. A simple example might be the agonist-induced depalmitoylation of the stimulatory G protein G<sub>s</sub>α that results in its translocation from the plasma membrane ([Wedegaertner and Bourne 1994](#)). This translocation, which can be either into the cytosol or into different membrane domains, can either amplify or attenuate signaling ([Allen et al. 2007](#)). A catalog of these protein shifts during disease or response to drug can thus be assembled.

G protein-coupled receptors comprise targets for the majority of drugs used in psychiatry. Curiously, many of

these drugs were thought to have a single site of action until a screening/informatics approach was applied. *Receptoromics* allows screening of compounds for their agonist or antagonist effects on receptors, measured through batteries of cells selectively expressing a single species of G protein-coupled receptor (or other receptor or transporter). Results from these studies have been both informative and surprising ([Strachan et al. 2006](#)). For example, atypical antipsychotics have been selected for their antagonist properties at the 5-HT<sub>2A</sub> receptor. Some of these drugs, such as olanzapine, have been associated with excessive weight gain, and this appears to be due to interaction with histamine H<sub>1</sub> receptors rather than being related to the therapeutic profile of the drug. Other effective antipsychotic drugs may owe their efficacy to actions at a panel of receptors that, when combined, contribute to a therapeutic whole ([Roth and Kroeze 2015](#)). The ability to screen libraries of compounds against a large number of receptor targets makes design and identification of new drugs an exciting possibility.

## Conclusion

---

Rapid advances in the identification of the human genome and in the methodology for genetic manipulation have combined to open a window into the brain. We are accumulating knowledge of human gene mutations and their connection to neurological and psychiatric diseases at a rapid pace. As genes are being identified, the proteins for which they code are also becoming known. This knowledge enables the pathogenic mechanism for some of these

diseases to become apparent. Understanding these maladies on the molecular level is likely to lead to new methods of diagnosis and novel approaches to therapy.

This chapter serves as a primer on the recent advances in our understanding of neural function both in health and in disease. It is beyond the scope of this chapter to cover these important areas in extensive detail, and readers are referred to outstanding textbooks that are entirely devoted to the topic ([Kandel 2013](#); [Nestler et al. 2015](#); [Squire 2013](#)). Here, we focus on the principles of neurotransmission that are critical for an understanding of the biological bases of major psychiatric disorders, as well as the mechanisms by which effective treatments may exert

their beneficial effects. In particular, our goal is to lay the groundwork for the subsequent chapters in this volume that focus on individual disorders and their treatments.

Although this chapter is intended to provide a general overview on neurotransmitter function, whenever possible, we emphasize the neuropsychiatric relevance of specific observations. We outline principles that are of fundamental importance to the study and practice of psychopharmacology. The figure legends contain additional details for the interested reader.

## What Are Neurotransmitters?

---

Several criteria have been established for a neurotransmitter, including that 1) it is synthesized and released from neurons; 2) it is released from nerve terminals in a chemically or pharmacologically identifiable form; 3) it interacts with postsynaptic receptors and brings about the same effects as are seen with stimulation of the presynaptic neuron; 4) its interaction with the postsynaptic receptor displays a specific pharmacology; and 5) its actions are terminated by active processes ([Kandel 2013](#); [Nestler et al. 2015](#); [Squire 2013](#)). However, our growing appreciation of the complexity of the central nervous system (CNS) and of the existence of numerous molecules that exert *neuromodulatory* and *neurohormonal* effects has blurred the classical definition of neurotransmitters somewhat, and even well-known neurotransmitters do not meet all these criteria under certain situations ([Cooper et al. 2003](#)).

Most neuroactive compounds are small polar molecules that are synthesized in the CNS via local machinery or are able to permeate the blood-brain barrier. To date, more than 50 endogenous substances have been found to be present in the brain that appear to be capable of functioning as neurotransmitters. There are many plausible explanations for why the brain would need so many transmitters and receptor subtypes to transmit messages. Perhaps the simplest explanation is that the sheer complexity of the CNS results in many afferent nerve terminals impinging onto a single neuron. This requires a neuron to be able to distinguish the multiple information-conveying inputs. Although this can be accomplished partially by spatial segregation, it is accomplished in large part by chemical coding of the inputs—that is, different chemicals convey different information. Moreover, as we discuss in detail later, the evolution of multiple receptors for a single neurotransmitter means that the same chemical can convey different messages depending on the receptor subtypes it acts on. Additionally, the firing pattern of neurons is a means of conveying information; thus, the firing activities of neurons in the brain differ widely, and a single neuron firing at different frequencies can even release different neuroactive compounds depending on the firing rate (e.g., the release of peptides often occurs at higher firing rates than that which is required to release monoamines). These multiple mechanisms to enhance the diversity of responses—chemical coding, spatial coding, frequency coding—are undoubtedly critical in endowing the CNS with its complex repertoire of physiological and behavioral responses ([Kandel 2013](#); [Nestler et al. 2015](#)). Finally, the existence of multiple neuroactive compounds also provides built-in safeguards to ensure that vital brain

circuits are able to partially compensate for loss of function of particular neurotransmitters.

---

## Receptors

---

An essential property of any living cell is its ability to recognize and respond to external stimuli. Cell surface receptors have two major functions: recognition of specific molecules (neurotransmitters, hormones, growth factors, and even sensory signals) and activation of “effectors.” Binding of the appropriate agonist (i.e., neurotransmitter or hormone) externally to the receptor alters the conformation (shape) of the protein. Cell surface receptors use a variety of membrane-transducing mechanisms to transform an agonist’s message into cellular responses. In neuronal systems, the most typical responses ultimately (in some cases rapidly, in others more slowly) involve changes in transmembrane voltage and hence neuronal changes in excitability. Collectively, the processes are referred to as *transmembrane signaling* or *signal transduction mechanisms*. This process is not restricted to neurons. For instance, astrocytes were once thought to be uninvolved in neurotransmission, but they have since been shown to possess volume-regulated Cl<sup>-</sup> anion channels, which work together with gap junction/hemichannels to permit efflux of amino acids such as taurine, glutamate, and aspartate in response to swelling due to brain injury ([Mulligan and MacVicar 2006](#); [Ye et al. 2009](#)).

Interestingly, although increasing numbers of potential neuroactive compounds and receptors continue to be identified, it has become clear that translation of the

extracellular signals (into a form that can be interpreted by the complex intracellular enzymatic machinery) is achieved through a relatively small number of cellular mechanisms. Generally speaking, these transmembrane signaling systems, and the receptors that use them, can be divided into four major groups ([Figure 2-1](#)):

1. Those that are relatively self-contained in structure and whose message takes the form of transmembrane ion fluxes (**ionotropic receptors**)
2. Those that are multicomponent in nature and generate intracellular second messengers (**G protein-coupled receptors**)
3. Those that contain intrinsic enzymatic activity (**receptor tyrosine kinases and phosphatases**)
4. Those that are cytoplasmic and translocate to the nucleus to directly regulate transcription (gene expression) after they are activated by lipophilic molecules (often hormones) that enter the cell (**nuclear receptors**)

**FIGURE 2-1.** Major receptor subtypes in the central nervous system.

See [Plate 4](#) to view this figure in color.

This figure depicts the four major classes of receptors in the CNS. **(A) Ionotropic receptors.** These receptors comprise multiple protein subunits that are combined in such a way as to create a central membrane pore through this complex, allowing the flow of ions. This type of receptor has a very rapid response time (milliseconds). The consequences of receptor stimulation (i.e., excitatory or inhibitory) depend on the types of ions that the receptor specifically allows to enter the cell. Thus, for example, Na<sup>+</sup> entry through the NMDA (*N*-methyl-D-aspartate) receptor depolarizes the neuron and brings about an excitatory response, whereas Cl<sup>-</sup> efflux through the  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor hyperpolarizes the neuron and brings about an inhibitory response. Illustrated here is the NMDA receptor regulating a channel permeable to Ca<sup>2+</sup>, Na<sup>+</sup>,

and  $K^+$  ions. The NMDA receptors also have binding sites for glycine,  $Zn^{2+}$ , phencyclidine, MK801/ketamine, and  $Mg^{2+}$ ; these molecules are able to regulate the function of this receptor. **(B) *G protein-coupled receptors*** (GPCRs). The majority of neurotransmitters, hormones, and even sensory signals mediate their effects via seven transmembrane domain-spanning receptors that are G protein-coupled. The amino terminus of the G protein is on the outside of the cell and plays an important role in the recognition of specific ligands; the third intracellular loop and carboxy terminus of the receptor play an important role in coupling to G proteins and are sites of regulation of receptor function (e.g., by phosphorylation). All G proteins are heterotrimers (consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits). The G proteins are attached to the membrane by isoprenoid moieties (fatty acid) via their  $\gamma$  subunits. Compared with the ionotropic receptors, GPCRs mediate a slower response (on the order of seconds). Detailed depiction of the activation of G protein-coupled receptors is given in [Figure 2-2](#). Here we depict a receptor coupled to the G protein  $G_s$  (the s stands for stimulatory to the enzyme adenylyl cyclase [AC]). Activation of such a receptor produces activation of AC and increases in cyclic adenosine monophosphate (cAMP) levels. G protein-coupled pathways exhibit major amplification properties, and, for example, in model systems researchers have demonstrated a 10,000-fold amplification of the original signal. The effects of cAMP are mediated largely by activation of protein kinase A (PKA). One major downstream target of PKA is CREB (cAMP response element-binding protein), which may be important to the mechanism of action of antidepressants. **(C) *Receptor tyrosine kinases***. These receptors are activated by neurotrophic factors and are able to bring about acute changes in synaptic function, as well as long-term effects on neuronal growth and survival. These receptors contain intrinsic tyrosine kinase activity. Binding of the ligand triggers receptor dimerization and transphosphorylation of tyrosine residues in its cytoplasmic domain,

which then recruits cytoplasmic signaling and scaffolding proteins. The recruitment of effector molecules generally occurs via interaction of proteins with modular binding domains SH2 and SH3 (named after homology to the src oncogenes–src homology domains); SH2 domains are a stretch of about 100 amino acids that allow high-affinity interactions with certain phosphotyrosine motifs. The ability of multiple effectors to interact with phosphotyrosines is undoubtedly one of the keys to the pleiotropic effects that neurotrophins can exert. Shown here is a tyrosine kinase receptor type B (TrkB), which upon activation produces effects on the Raf, MEK (mitogen-activated protein kinase/ERK), extracellular response kinase (ERK), and ribosomal S6 kinase (RSK) signaling pathway. Some major downstream effects of RSK are CREB and stimulation of factors that bind to the AP-1 site (c-Fos and c-Jun). **(D) Nuclear receptors.** These receptors are transcription factors that regulate the expression of target genes in response to steroid hormones and other ligands. Many hormones (including glucocorticoids, gonadal steroids, and thyroid hormones) are able to rapidly penetrate into the lipid bilayer membrane, because of their lipophilic composition, and thereby directly interact with these cytoplasmic receptors inside the cell. Upon activation by a hormone, the nuclear receptor–ligand complex translocates to the nucleus, where it binds to specific DNA sequences, referred to as *hormone responsive elements* (HREs), and regulates gene transcription. Nuclear receptors often interact with a variety of coregulators that promote transcriptional activation when recruited (coactivators) and those that attenuate promoter activity (corepressors). However, nongenomic effects of neuroactive steroids have also been documented, with the majority of evidence suggesting modulation of ionotropic receptors. This figure illustrates both the genomic and the nongenomic effects. A more extensive and continuously updated synopsis of these and many other receptors and ligands can be found at the International Union of Basic and Clinical Pharmacology/British Pharmacological Society Guide to Pharmacology Web site ([www.guidetopharmacology.org](http://www.guidetopharmacology.org)) and associated publications (Alexander et al. 2013a, 2013b, 2013c, 2013d, 2013e, 2013f). We review the four major groups in the following subsections.

## Ionotropic Receptors

The first class of receptors contains in their molecular complex an intrinsic *ion channel*. Receptors of this class include those for several amino acids, including glutamate (e.g., the NMDA [*N*-methyl-D-aspartate] receptor), GABA ( $\gamma$ -aminobutyric acid via the GABA<sub>A</sub> receptor), and the nicotinic acetylcholine (nACh) receptor and the serotonin type 3 (5-HT<sub>3</sub>) receptor. Ion channels are integral membrane proteins that are directly responsible for the electrical activity of the nervous system by virtue of their regulation of the movement of ions across membranes. Receptors containing intrinsic ion channels have been called *ionotropic* and are generally composed of four or five subunits that open transiently when a neurotransmitter binds, allowing ions to flow into (e.g., Na<sup>+</sup>, Ca<sup>2+</sup>, Cl<sup>-</sup>) or out

of (e.g.,  $K^+$ ) the neuron, thereby generating synaptic potential (see [Figure 2-1](#)).

Often, the ionotropic receptors are composed of different combinations of various subunits, thereby providing the system with considerable flexibility. For example, there is extensive research into the potential development of an anxiolytic that is devoid of sedative effects by targeting GABA<sub>A</sub> receptor subunits present in selected brain regions ([Salerno et al. 2012](#); [Taliani et al. 2009](#)). In general, neurotransmission that is mediated by ionotropic receptors is very fast, with ion channels opening and closing within milliseconds, and these receptors regulate much of the tonic excitatory (e.g., glutamate-mediated) and inhibitory (e.g., GABA-mediated) activity in the CNS; as we discuss in the “Neurotransmitter and Neuropeptide Systems” section later in this chapter, many of the classic neurotransmitters (e.g., monoamines) exert their effects on a slower time scale and are therefore often considered to be modulatory in their effects.

## G Protein–Coupled Receptors

Most receptors in the CNS do not have intrinsic ionic conductance channels within their structure but instead regulate cellular activity by the generation of various “second messengers.” Receptors of this class generally do not interact directly with the various second-messenger-generating enzymes but transmit information to the appropriate “effector” by the activation of interposed coupling proteins. These are the G protein-coupled receptor families, and they provide a slower onset, but longer duration of signaling, compared with ionotropic

receptors ([Squire 2013](#)). The *G protein-coupled receptors* (GPCRs, which constitute more than 80% of all known receptors in the body and number about 800 in humans) all span the plasma membrane seven times and have three intracellular loops and three extracellular loops (see [Figure 2-1](#)) ([Alexander et al. 2013b](#)). G proteins are so named because of their ability to bind the guanine nucleotides guanosine triphosphate and guanosine diphosphate. Receptors coupled to G proteins include those for dopamine, serotonin, acetylcholine, various peptides, and even sensory signals such as light and odorants.

GPCRs have increasingly become the focus of extensive research in psychiatry ([Catapano and Manji 2007](#)). The amino terminus is on the outside of the cell and plays a critical role in recognition of the ligand, which can be a small molecule, peptide, or large protein; the carboxy terminus and third intracellular loop are inside the cell and regulate coupling to different G proteins, “cross-talk” between receptors, and desensitization (see [Figure 2-1](#)) ([Alexander et al. 2013b](#)). Although the bimodal model of ligands switching the GPCR “on” or “off” is appealing, an individual GPCR can actually assume many different conformations, which influences the nature of the ligand-receptor interaction and the predominant complex signal generated in a particular cell type; this concept is called ligand-induced selective signaling ([Millar and Newton 2010](#)). Differential oligomerization, differential phosphorylation, signaling through molecules other than G proteins, and second-messenger independent signaling together add even more complexity for future GPCR research ([Kandel 2013](#); [Millar and Newton 2010](#)).

In conclusion, many classes and subtypes of G proteins exist, playing key roles in amplifying and integrating

signals.

## Autoreceptors and Heteroreceptors

*Autoreceptors* are receptors located on neurons that produce the endogenous ligand for that particular receptor (e.g., a serotonergic receptor on a serotonergic neuron). By contrast, *heteroreceptors* are receptor subtypes that are present on neurons that do not contain an endogenous ligand for that particular receptor subtype (e.g., a serotonergic receptor located on a dopaminergic neuron).

Two major classes of autoreceptors play very important roles in fine-tuning neuronal activity. *Somatodendritic autoreceptors* are present on cell bodies and dendrites and exert critical roles in regulating the firing rate of neurons. In general, activation of somatodendritic autoreceptors (e.g.,  $\alpha_2$ -adrenergic receptors for noradrenergic neurons, 5-HT<sub>1A</sub> receptors for serotonergic neurons, or dopamine type 2 [D<sub>2</sub>] receptors for dopaminergic neurons) inhibits the firing rate of the neurons by opening K<sup>+</sup> channels and by reducing cyclic adenosine monophosphate (cAMP) levels, both of which may be important in psychiatric disease. For instance, TREK-1 is a background K<sup>+</sup> channel regulator protein important in serotonin transmission and potentially in moodlike behavior regulation in mice ([Heurteaux et al. 2006](#)). This exemplifies how fundamental mechanisms of neuronal transmission such as K<sup>+</sup> channels, which regulate membrane potentials, may relate to global alterations in brain functioning relevant to psychiatry.

The second major class of autoreceptors, *nerve terminal autoreceptors*, play an important role in regulating the amount of neurotransmitter released per nerve impulse, generally by closing nerve terminal Ca<sup>2+</sup> channels. Both of

these types of autoreceptors are typically members of the GPCR family. Neurotransmitter release is known to be triggered by influx and alterations of intracellular calcium, with functioning of three types of SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein [SNAP] receptor) proteins mediating a critical role. The distinct kinetics of neurotransmitter release modulators, such as botulinum and tetanus neurotoxins, induce prominent alterations in synaptobrevin and syntaxin, leading to calcium-independent mechanisms of neurotransmitter regulation ([Sakaba et al. 2005](#)). Most synapses are dependent on influx of  $\text{Ca}^{2+}$  through voltage-gated calcium channels for presynaptic neurotransmitter release; however, in the retina, this influx of calcium occurs via glutamatergic  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors ([Chávez et al. 2006](#)). Beyond the receptor level, presynaptic SAD (synapses of amphids defective, originally identified as a regulator of neuronal polarity in the *Caenorhabditis elegans* worm model), an intracellular serine threonine kinase, is associated with the active zone cytomatrix that regulates neurotransmitter release, and SAD kinases in presynaptic neurons also control the maturation and arborization of synapses in the central and peripheral nervous systems ([Inoue et al. 2006](#); [Lilley et al. 2014](#)). These data further exemplify the dynamic nature of basic processes involved in neurotransmitter regulation that may possibly aid in advancing treatment of psychopathology.

## **GPC Receptor Regulation and Trafficking**

The mechanism by which GPCRs translate extracellular signals into cellular changes was once envisioned as a simple linear model. It is now known, however, that the

activity of GPCRs is subject to at least three additional principal modes of regulation: desensitization, downregulation, and trafficking (Carman and Benovic 1998) (Figure 2-2). *Desensitization*, the process by which cells rapidly adapt to stimulation by agonists, is generally believed to occur by two major mechanisms: homologous and heterologous.

**FIGURE 2-2.** G protein-coupled receptors and G protein activation.

*See Plate 5 to view this figure in color.*

All G proteins are heterotrimers consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits. The receptor shuttles between a low-affinity form that is not coupled to a G protein and a high-affinity form that is coupled to a G protein. **(A)** At rest, G proteins are largely in their inactive state, namely, as  $\alpha\beta\gamma$  heterotrimers, which have GDP (guanosine diphosphate) bound to the  $\alpha$  subunit. **(B)** When a receptor is activated by a neurotransmitter, it undergoes a conformational (shape) change, forming a transient state referred to as a *high-affinity ternary complex*, comprising the agonist, the receptor in a

high-affinity state, and the G protein. A consequence of the receptor interaction with the G protein is that the GDP comes off the G protein  $\alpha$  subunit, leaving a very transient empty guanine nucleotide binding domain. **(C)** Guanine nucleotides (generally GTP) quickly bind to this nucleotide binding domain; thus, one of the major consequences of active receptor-G protein interaction is to facilitate guanine nucleotide exchange—this is basically the “on switch” for the G protein cycle. **(D)** A family of GTPase-activating proteins for G protein-coupled receptors has been identified, and they are called regulators of G protein signaling (RGS) proteins. Since activating GTPase activity facilitates the “turn off” reaction, these RGS proteins are involved in dampening the signal. Binding of GTP to the  $\alpha$  subunit of G proteins results in subunit dissociation, whereby the  $\alpha$ -GTP dissociates from the  $\beta\gamma$  subunits. Although not covalently bound, the  $\beta$  and  $\gamma$  subunits remain tightly associated and generally function as dimers. The  $\alpha$ -GTP and  $\beta\gamma$  subunits are now able to activate multiple diverse effectors, thereby propagating the signal. While they are in their active states, the G protein subunits can activate multiple effector molecules in a “hit and run” manner; this results in major signal amplification (i.e., one active G protein subunit can activate multiple effector molecules). The activated G protein subunits also dissociate from the receptor, converting the receptor to a low-affinity conformation and facilitating the dissociation of the agonist from the receptor. The agonist can now activate another receptor, and this also results in signal amplification. Together, these processes have been estimated to produce a 10,000-fold amplification of the signal in certain models. **(E)** Interestingly, the  $\alpha$  subunit has intrinsic GTPase activity, which cleaves the third phosphate group from GTP (G-P-P-P) to GDP (G-P-P). Since  $\alpha$ -GDP is an inactive state, the GTPase activity serves as a built-in timing mechanism, and this is the “turn off” reaction. **(F)** The reassociation of  $\alpha$ -GDP with  $\beta\gamma$  is

thermodynamically favored, and the reformation of the inactive heterotrimer ( $\alpha\beta\gamma$ ) completes the G protein cycle.

*Homologous desensitization* is receptor specific; that is, only the receptor actively being stimulated becomes desensitized. This form of desensitization occurs via a family of kinases known as G protein-coupled kinases. When a receptor activates a G protein and causes dissociation of the  $\alpha$  subunit from the  $\beta\gamma$  subunits, the  $\beta\gamma$  subunits are able to provide an “anchoring surface” for the G protein-coupled kinases to allow them to come into the proximity of the activated receptor and phosphorylate it. This phosphorylation then recruits another family of proteins known as *arrestins*, which physically interfere with the coupling of the phosphorylated receptor and the G protein, thereby dampening the signal. This form of desensitization is very rapid and usually transient (i.e., the receptors get dephosphorylated and return to the baseline state). However, if the stimulation of the receptor is excessive and prolonged, it leads to an internalization of the receptor, and often its degradation, a process referred to as *downregulation*.

*Heterologous desensitization* is not receptor specific and is mediated by second-messenger kinases such as protein kinase A (PKA) and protein kinase C (PKC). Thus, when a receptor activates PKA, the activated PKA is capable of phosphorylating (and thereby desensitizing) not only that particular receptor but also other receptors that are present in proximity and have the correct phosphorylation motif, thereby producing heterologous desensitization.

After prolonged or repeated activation of receptors by agonist ligands, the process of receptor *downregulation* is observed. Downregulation is associated with a reduced

number of receptors detected in cells or tissues, thereby leading to attenuation of cellular responses ([Carman and Benovic 1998](#)). The process of GPCR sequestration is mediated by a well-characterized endocytic pathway involving the concentration of receptors in clathrin-coated pits and subsequent internalization and recycling back to the plasma membrane ([Tsao and von Zastrow 2000](#)). Endocytosis can thus clearly serve as a primary mechanism to attenuate signaling by rapidly and reversibly removing receptors from the cell surface. However, endocytosis and receptor trafficking also mediate GPCR signaling by way of certain effector pathways, most notably mitogen-activated protein (MAP) kinase cascades. Evidence also indicates that endocytosis of GPCRs may be required for certain signal transduction pathways leading to the nucleus ([Tsao and von Zastrow 2000](#)). These diverse functions of GPCR endocytosis and trafficking lead to unexpected insights into the biochemical and functional properties of endocytic vesicles. Indeed, there is considerable excitement about our growing understanding of the diverse molecular mechanisms for signaling specificity and receptor trafficking and the possibility that this knowledge could lead to new selective therapeutics.

## Receptor Tyrosine Kinases

The receptor tyrosine kinases, as their name implies, contain intrinsic tyrosine kinase activity and are generally used by growth factors, such as neurotrophic factors, and cytokines. Binding of an agonist initiates receptor dimerization and transphosphorylation of tyrosine residues in its cytoplasmic domain ([Patapoutian and Reichardt 2001](#))

(see [Figure 2-1](#)). The phosphotyrosine residues of the receptor function as binding sites for recruiting specific cytoplasmic signaling and scaffolding proteins. The ability of multiple effectors to interact with phosphotyrosines is undoubtedly one of the keys to the pleiotropic effects that neurotrophins can exert. These pleiotropic and yet distinct effects of growth factors are mediated by varying degrees of activation of three major signaling pathways: the MAP kinase pathway, the phosphoinositide-3 (PI<sub>3</sub>) kinase pathway, and the phospholipase C (PLC)- $\gamma$ 1 pathway. These pathways are part of complex secondary messaging systems of the cell, which are beyond the scope of this chapter.

## Nuclear Receptors

Nuclear receptors are transcription factors that regulate the expression of target genes in response to steroid hormones and other ligands. Many hormones (including glucocorticoids, gonadal steroids, and thyroid hormones) are able to rapidly penetrate into the lipid bilayer membrane because of their lipophilic composition, and thereby directly interact with these cytoplasmic receptors inside the cell (see [Figure 2-1](#)). On activation by a hormone, the nuclear receptor-ligand complex translocates to the nucleus, where it binds to specific DNA sequences referred to as *hormone-responsive elements*, and subsequently regulates gene transcription ([Mangelsdorf et al. 1995](#); [Truss and Beato 1993](#)). Nuclear receptors often interact with a variety of coregulators that promote transcriptional activation when recruited (*coactivators*) and those that attenuate promoter activity (*corepressors*). Numerous

nuclear receptors have been identified, as reviewed elsewhere ([Alexander et al. 2013e](#)).

With this broad overview of neurotransmitters and receptor subtypes, we now turn to a discussion of selected individual neurotransmitters and their receptors.

## Neurotransmitter and Neuropeptide Systems

---

### Serotonergic System

Largely on the basis of the observation that most effective antidepressants and antipsychotics target these systems, the monoaminergic systems (e.g., serotonin, norepinephrine, dopamine) have been extensively studied. Serotonin was given that name because of its activity as an endogenous vasoconstrictor in blood serum ([Rapport et al. 1948](#)). It was later acknowledged as being the same molecule (secretine) that is found in the intestinal mucosa and that is “secreted” by chromaffin cells ([Brodie 1900](#)). Following these findings, serotonin later was characterized as a neurotransmitter in the CNS ([Bogdanski et al. 1956](#)).

Serotonin-producing cell bodies in the brain are localized to the central gray, in the surrounding reticular formation, and in cell clusters located in the center, and thus the name *raphe* (from Latin, meaning “midline”) was adopted ([Figure 2-3A](#)). The dorsal raphe, the largest brain stem serotonin nucleus, contains approximately 50% of the total serotonin neurons in the mammalian CNS; in contrast, the medial raphe comprises 5% ([Descarries et al. 1982](#); [Wiklund and](#)

[Björklund 1980](#)). Serotonergic neurons project widely throughout the CNS rather than to discrete anatomical locations (as the dopaminergic neurons appear to do; see [Figure 2-4A](#) later in this chapter), leading to the suggestion that serotonin exerts a major *modulatory* role throughout the CNS ([Reader 1980](#)). Interestingly, evidence suggests that infralimbic and prelimbic regions of the ventromedial prefrontal cortex (vmPFC) in rats are responsible for detecting whether a stressor is under the organism's control. When a stressor is controllable, stress-induced activation of the dorsal raphe nucleus is inhibited by the vmPFC, and the behavioral sequelae of the uncontrollable stress response are blocked ([Amat et al. 2005](#)). The ability to regulate serotonin neuron activity and function has been a major ongoing focus of psychiatric disorder research and treatments. Lysergic acid diethylamide, a hallucinogen, has a chemical structure similar to that of serotonin, and monoamine oxidase (MAO) inhibitors (MAOIs), which are classic antidepressants, increase the levels of monoamines such as serotonin in the synapse ([Squire 2013](#)).

**FIGURE 2-3.** The serotonergic system.

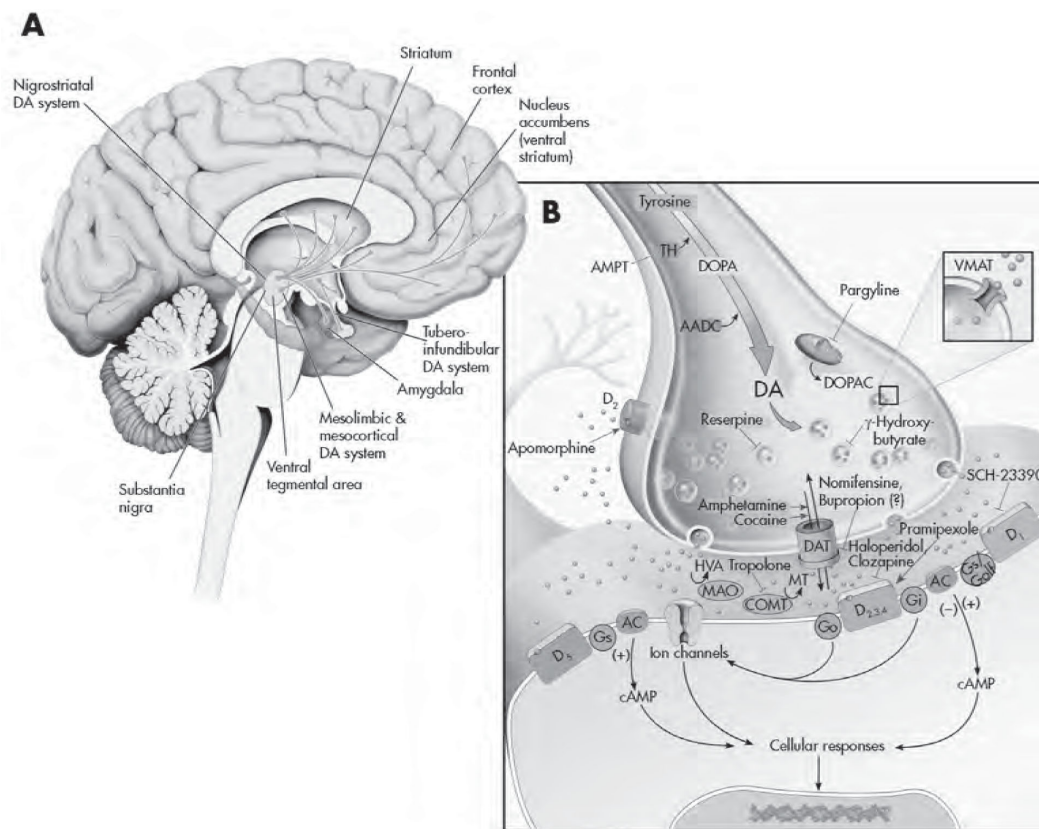

*See Plate 6 to view this figure in color.*

This figure depicts the location of the major serotonin (5-HT)-producing cells (raphe nuclei) innervating brain structures **(A)**, and various cellular regulatory processes involved in serotonergic neurotransmission **(B)**. 5-HT neurons project widely throughout the CNS and innervate virtually every part of the neuroaxis. L-Tryptophan, an amino acid actively transported into presynaptic 5-HT-containing terminals, is the precursor for 5-HT. It is converted to 5-hydroxytryptophan (5-HTP) by the rate-limiting enzyme tryptophan hydroxylase (TrpH). This enzyme is effectively inhibited by the drug *p*-chlorophenylalanine (PCPA). Aromatic amino acid decarboxylase (AADC) converts 5-HTP to 5-HT. Once released from the presynaptic terminal, 5-HT can interact with a variety (15 different types) of presynaptic and postsynaptic receptors.

Presynaptic regulation of 5-HT neuron firing activity and release occurs through somatodendritic 5-HT<sub>1A</sub> (not shown) and 5-HT<sub>1B,1D</sub> autoreceptors, respectively, located on nerve terminals. Sumatriptan is a 5-HT<sub>1B,1D</sub> receptor agonist. (The antimigraine effects of this agent are likely mediated by local activation of this receptor subtype on blood vessels, which results in their constriction.) Buspirone is a partial 5-HT<sub>1A</sub> receptor agonist that activates both pre- and postsynaptic receptors. Cisapride is a preferential 5-HT<sub>4</sub> receptor agonist that is used to treat irritable bowel syndrome as well as nausea associated with antidepressants. The binding of 5-HT to G protein receptors (G<sub>o</sub>, G<sub>i</sub>, etc.) that are coupled to adenylyl cyclase (AC) and phospholipase C-β (PLC-β) will result in the production of a cascade of second-messenger and cellular effects. Lysergic acid diethylamide (LSD) likely interacts with numerous 5-HT receptors to mediate its effects. Pharmacologically this ligand is often used as a 5-HT<sub>2</sub> receptor agonist in receptor-binding experiments. Ondansetron is a 5-HT<sub>3</sub> receptor antagonist that is marketed as an antiemetic agent for chemotherapy patients but is also given to counteract side effects produced by antidepressants in some patients. 5-HT has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron through 5-HT transporters (5-HTTs). Once inside the neuron, it can either be repackaged into vesicles for reuse or undergo enzymatic catabolism. The selective 5-HT reuptake inhibitors (SSRIs) and older-generation tricyclic antidepressants (TCAs) are able to interfere/block the reuptake of 5-HT. 5-HT is then metabolized to 5-hydroxyindoleacetic acid (5-HIAA) by monoamine oxidase (MAO), located on the outer membrane of mitochondria or sequestered and stored in secretory vesicles by vesicular monoamine transporters (VMATs). Reserpine causes a depletion of 5-HT in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this agent). Tranylcypromine is an MAO inhibitor (MAOI) and an effective antidepressant.

Fenfluramine (an anorectic agent) and 3,4-methylenedioxymethamphetamine (MDMA; “Ecstasy”) are able to facilitate 5-HT release by altering 5-HTT function. cAMP=cyclic adenosine monophosphate; DAG=diacylglycerol; IP<sub>3</sub>=inositol-1,4,5-triphosphate.

**FIGURE 2-4.** The dopaminergic system.

*See Plate 7 to view this figure in color.*

This figure depicts the dopaminergic projections throughout the brain **(A)** and various regulatory processes involved in

dopaminergic neurotransmission **(B)**. The amino acid L-tyrosine is actively transported into presynaptic dopamine (DA) nerve terminals, where it is ultimately converted into DA. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase (TH).  $\alpha$ -Methyl-*p*-tyrosine (AMPT) is a competitive inhibitor of tyrosine hydroxylase and has been used to assess the impact of reduced catecholaminergic function in clinical studies. The production of DA requires that L-aromatic amino acid decarboxylase (AADC) act on L-dopa. Thus, the administration of L-dopa to patients with Parkinson's disease bypasses the rate-limiting step and is able to produce DA quite readily. DA has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron through DA transporters (DATs). DA is then metabolized to dihydroxyphenylalanine (DOPAC) by intraneuronal monoamine oxidase (MAO; preferentially by the MAO-B subtype) located on the outer membrane of mitochondria, or is sequestered and stored in secretory vesicles by vesicular monoamine transporters (VMATs). Reserpine causes a depletion of DA in vesicles by interfering and irreversibly damaging uptake and storage mechanisms.  $\gamma$ -Hydroxybutyrate inhibits the release of DA by blocking impulse propagation in DA neurons. Pargyline inhibits MAO and may have efficacy in treating parkinsonian symptoms by augmenting DA levels through inhibition of DA catabolism. Other clinically used inhibitors of MAO are nonselective and thus likely elevate the levels of DA, norepinephrine, and serotonin. Once released from the presynaptic terminal (because of an action potential and calcium influx), DA can interact with five different G protein-coupled receptors (D<sub>1</sub>-D<sub>5</sub>), which belong to either the D<sub>1</sub> or D<sub>2</sub> receptor family. Presynaptic regulation of DA neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal D<sub>2</sub> autoreceptors, respectively. Pramipexole is a D<sub>2</sub>/D<sub>3</sub> receptor agonist and has been documented to have efficacy as an

augmentation strategy in cases of treatment-resistant depression and in the management of Parkinson's disease. The binding of DA to G protein receptors ( $G_o$ ,  $G_i$ , etc.) positively or negatively coupled to adenylyl cyclase (AC) results in the activation or inhibition of this enzyme, respectively, and the production of a cascade of second-messenger and cellular effects (see diagram). Apomorphine is a  $D_1/D_2$  receptor agonist that has been used clinically to aid in the treatment of Parkinson's disease. (SKF-82958 is a pharmacologically selective  $D_1$  receptor agonist.) SCH-23390 is a  $D_1/D_5$  receptor antagonist. There are likely physiological differences between  $D_1$  and  $D_5$  receptors, but the current unavailability of selective pharmacological agents has precluded an adequate differentiation thus far. Haloperidol is a  $D_2$  receptor antagonist, and clozapine is a nonspecific  $D_2/D_4$  receptor antagonist (both are effective antipsychotic agents). Once inside the neuron, DA can either be repackaged into vesicles for reuse or undergo enzymatic catabolism. Nomifensine is able to interfere/block the reuptake of DA. The antidepressant bupropion has affinity for the dopaminergic system, but it is not known whether this agent mediates its effects through DA or possibly by augmenting other monoamines. DA can be degraded to homovanillic acid (HVA) through the sequential action of catechol-*O*-methyltransferase (COMT) and MAO. Tropolone is an inhibitor of COMT. Evidence suggests that the COMT gene may be linked to schizophrenia ([Akil et al. 2003](#)). cAMP=cyclic adenosine monophosphate; DOPA=dihydroxyphenylalanine; MT=methoxytyramine;

The precursor for serotonin synthesis is L-tryptophan, an amino acid that comes primarily from the diet and crosses the blood-brain barrier through a carrier for large neutral amino acids. Tryptophan hydroxylase is the rate-limiting enzyme in serotonin biosynthesis ([Figure 2-3B](#)), and polymorphisms in this enzyme have been extensively investigated in psychiatric disorders, with equivocal results. A more fruitful research strategy in humans has been tryptophan depletion via dietary restriction to study the role of serotonin in the pathophysiology and treatment of psychiatric disorders ([Bell et al. 2001](#); [van Donkelaar et al. 2011](#)). These studies have indicated that acute tryptophan depletion (ATD) produces a rapid depressive relapse in patients taking selective serotonin reuptake inhibitors (SSRIs) but not in those taking norepinephrine reuptake inhibitors; the data suggesting induction of depressive symptoms in remitted patients or individuals with family histories of mood disorders are more equivocal ([Bell et al. 2001](#)). Findings similar to those from ATD depression studies also have been identified in numerous studies of panic disorder, whereby healthy subjects with no history of panic disorder, or patients with panic disorder in remission, were not very sensitive to ATD, but patients with unremitted panic disorder were extremely sensitive to carbon dioxide challenges ([Sobczak and Schruers 2014](#)). Some of the inconsistencies of the ATD findings in the literature may have been due to the various formulations of the tryptophan depletion amino acid cocktails used, but more surprising are suggestions that the classic ATD cocktails may not have been depleting extracellular synaptic serotonin levels after all but may have been working through other molecular mechanisms as described elsewhere ([Sobczak and Schruers 2014](#); [van Donkelaar et](#)

al. 2011). Nevertheless, numerous studies in the literature suggest that, in general, low levels of serotonin in the plasma and/or cerebrospinal fluid (CSF) correlate with depression, impulsivity, aggression, alcohol dependence, suicide attempts, completed suicides, and violent suicides (Bortolato et al. 2013; Moberg et al. 2011; Oo et al. 2016; Purselle and Nemeroff 2003; Ruljancic et al. 2011, 2013; Spreux-Varoquaux et al. 2001). Serotonin dysfunction-related endophenotypes that could predict patients at risk for suicide are being explored, including fenfluramine challenges leading to poor prolactin release, increased time spent in rapid eye movement (REM) sleep stages, increased loudness-dependent auditory evoked potentials, and increased frontal cortex P300 (Lee and Kim 2011). Furthermore, postmortem studies in depressed bipolar patients who completed suicide found lower serotonin and norepinephrine activity (Wiste et al. 2008).

More sophisticated molecular approaches targeting individual serotonin receptors and transporters are described in the following subsections.

## Serotonin Transporters

As is the case for many classic neurotransmitters, termination of the effects of serotonin in the synaptic cleft is brought about in large part by an active reuptake process mediated by the serotonin transporter (5-HTT). Serotonin is taken up into the presynaptic terminals, where it is metabolized by the enzyme MAO or sequestered into secretory vesicles by the vesicle monoamine transporter (see Figure 2-3B). This presumably underlies the mechanism by which MAOIs initiate their therapeutic effects; that is, the blockade of monoamine breakdown results in an increase in the available pool for release when

an action potential invades the nerve terminal. It is now well established that many tricyclic antidepressants and SSRIs exert their initial primary pharmacological effects by binding to the 5-HTT and blocking serotonin reuptake, thereby increasing the intrasynaptic levels of serotonin, which initiates a cascade of downstream effects (see [Figure 2-3B](#) for details). It has been hypothesized that the first step in serotonin transport involves the binding of serotonin to the 5-HTT and then a cotransport with  $\text{Na}^+$ , and the second step involves the translocation of  $\text{K}^+$  across the membrane to the outside of the cell. SSRIs bind to the same site on the transporter as serotonin itself. Elegant biochemical and mutagenesis experiments have elucidated a leucine transporter from bacterial species, providing information that helped unravel the mechanism by which mammalian transporters couple ions and substrates to mediate neurotransmitter clearance. The crystal structure for sodium- and chloride-dependent neurotransmitter transporters (including transporters for serotonin [SERT], dopamine [DAT], norepinephrine [NET], glycine [GlyT1b], and GABA [GAT1]) with the L-leucine binding sites for  $\text{Na}^+$  ions also has been elucidated ([Henry et al. 2006](#); [Yamashita et al. 2005](#)).

In the brain, 5-HTTs have been radiolabeled with [ $^3\text{H}$ ]-imipramine ([Hrdina et al. 1985](#); [Langer et al. 1980](#)) and with SSRIs such as [ $^3\text{H}$ ]cyanoimipramine ([Wolf and Bobik 1988](#)), [ $^3\text{H}$ ]paroxetine ([Habert et al. 1985](#)), and [ $^3\text{H}$ ]citalopram ([D'Amato et al. 1987](#)). The regional distribution of 5-HTT corresponds to discrete regions of rat brain known to contain cell bodies of serotonin neurons and synaptic axon terminals, most notably the cerebral cortex, neostriatum, thalamus, and limbic areas ([Cooper et al.](#)

2003; Hrdina et al. 1985; Madden 2002). The specific cellular localization of 5-HTT in the CNS also has been accomplished by using site-specific antibodies (Lawrence et al. 1995a). Immunohistochemical studies that used antibodies against the serotonin carrier have reported both neuronal and glial staining in areas of the rat brain containing serotonin somata and terminals (i.e., dorsal raphe and hippocampus) (Lawrence et al. 1995b). Experimental alterations of 5-HTT in young mice for a brief period during early development indicate abnormal emotional behavior in the same mice later in life, similar to the phenotype in mice in which 5-HTT is deficient throughout life (Ansorge et al. 2004). This suggests the necessity of serotonin early in emotional development and provides a possible mechanism by which genetic changes in the 5-HTT system may lead to susceptibility to develop psychiatric diseases such as depression (Caspi et al. 2003). Furthermore, serotonin uptake ability has been documented in primary astrocyte cultures (Kimelberg and Katz 1985) and has been postulated to account for considerable serotonin uptake in the frontal cortex and periventricular region (Ravid et al. 1992).

Because 5-HTT is transcribed from a single copy gene, abnormalities in platelet 5-HTT are thought to reflect CNS abnormalities (Owens and Nemeroff 1998). Several studies on platelet 5-HTT density have been undertaken using [<sup>3</sup>H]imipramine binding or [<sup>3</sup>H]paroxetine binding in mood disorders. Although the results of these studies are not entirely consistent, in total the results suggest that the receptor density value for platelet serotonin density is significantly lower in depressed subjects compared with healthy control subjects (Owens and Nemeroff 1998). The distribution of SERT (5-HTT) in the postmortem human

brain was found to be highest in the thalamus, amygdala, putamen, globus pallidus externa, lateral geniculate body, hippocampus, and caudate, with the lowest amounts in the cerebral cortex and minimal levels in the cerebellum and white matter ([Kish et al. 2005](#)).

Numerous studies have examined suicide risk related to individual genetic polymorphisms in SERT. For example, the serotonin-transporter-linked polymorphic region (5-HTTLPR) short S allele, which decreases presynaptic 5-HTT expression and thereby decreases serotonin reuptake and has an interaction with childhood abuse to increase lifetime depression risk, has nevertheless yielded contradictory results related to suicide risk, likely because of other confounding polymorphisms ([Purselle and Nemeroff 2003](#); [Ressler et al. 2010](#)). In patients with major depressive disorder (MDD) who attempted suicide, positron emission tomographic (PET) scanning with the [ $^{11}\text{C}$ ]N,N-dimethyl-2-(2-amino-4-cyanophenylthio) benzylamine ([ $^{11}\text{C}$ ]DASB) ligand indicated that SERT (5-HTT) levels were lower in the midbrain regions ([Miller et al. 2013](#)). In bipolar I patients with depression who completed suicide, a nearly 50% decrease in serotonin and norepinephrine activity was observed related to the locus coeruleus in postmortem brain studies, as compared with unipolar depressed patients who completed suicide and matched control subjects ([Wiste et al. 2008](#)). Three different antidepressants, sertraline (SSRI), citalopram (SSRI), and venlafaxine (serotonin-norepinephrine reuptake inhibitor), at clinical dosages in living patients were shown with PET ligand [ $^{11}\text{C}$ ]DASB to have 85% occupancy of SERT, effectively blocking SERT-mediated reuptake of free serotonin in the synapse and increasing serotonin synaptic levels ([Voineskos et al. 2007](#)). In summary, multiple

mechanisms can lead to insufficient levels of serotonin in neuronal synapses, which contributes significantly to the risk for depression and for suicide.

## Serotonin Receptors

In 1957, the existence of two separate serotonin receptors was first proposed, primarily because of the opposing phenomenon this neurotransmitter produces, in reference to cholinergic mediation of smooth muscle contraction ([Gaddum and Picarelli 1957](#)). Through the use of more precise molecular cloning and pharmacological and biochemical studies, seven distinct serotonin receptor families have been identified (5-HT<sub>1-7</sub>), many of which contain several subtypes. With the exception of the 5-HT<sub>3</sub> receptor, which is an excitatory ionotropic receptor, all the other serotonin receptors are GPCRs. The 5-HT<sub>1A,B,D,E,F</sub> receptors are negatively coupled to adenylyl cyclase; the 5-HT<sub>2A,B,C</sub> subtypes are positively coupled to PLC; and the 5-HT<sub>4</sub>, 5-HT<sub>5</sub>, 5-HT<sub>6</sub>, and 5-HT<sub>7</sub> subtypes are positively coupled to adenylyl cyclase (see [Figure 2-3B](#)) ([Humphrey et al. 1993](#); [Nestler et al. 2015](#)). When all types and subtypes are counted, 13 serotonin receptors are identified in humans ([Nestler et al. 2015](#)).

**5-HT<sub>1</sub> receptors.** 5-HT<sub>1A</sub> receptors are found in particularly high density in several limbic structures, including the hippocampus, septum, amygdala, and entorhinal cortex, as well as on serotonergic neuron cell bodies, where they serve as autoreceptors regulating serotonin neuronal firing rates ([Blier et al. 1998](#); [Cooper et al. 2003](#); [Pazos et al. 1985](#)). The highest density of labeling is found in the dorsal raphe, with lower densities observed

in the remaining raphe nuclei ([Pazos et al. 1985](#)). The density and messenger RNA (mRNA) expression of 5-HT<sub>1A</sub> receptors appear insensitive to reductions in serotonin transmission associated with lesioning the raphe or administering the serotonin-depleting agent *p*-chlorophenylalanine. Similarly, elevation of serotonin transmission, resulting from chronic administration of an SSRI or MAOI, does not consistently alter 5-HT<sub>1A</sub> receptor density or mRNA in the cortex, hippocampus, amygdala, or hypothalamus. In contrast to the insensitivity to serotonin, 5-HT<sub>1A</sub> receptor density is downregulated by adrenal steroids. Postsynaptic 5-HT<sub>1A</sub> receptor gene expression is under tonic inhibition by adrenal steroids in the hippocampus and some other regions. Thus, in rodents, hippocampal 5-HT<sub>1A</sub> receptor mRNA expression is increased by adrenalectomy and decreased by corticosterone administration or chronic stress. The stress-induced downregulation of 5-HT<sub>1A</sub> receptor expression is prevented by adrenalectomy. Mineralocorticoid receptor stimulation has the most potent effect on downregulating 5-HT<sub>1A</sub> receptors, although glucocorticoid receptor stimulation also contributes to this effect.

In addition to being expressed on neurons, postsynaptic 5-HT<sub>1A</sub> receptors are also abundantly expressed by astrocytes and some other glia ([Whitaker-Azmitia et al. 1990](#)) (see [Figure 2-7](#) later in this chapter). Stimulation of astrocyte-based 5-HT<sub>1A</sub> sites causes astrocytes to acquire a more mature morphology and to release the trophic factor S-100 $\beta$ , which promotes growth and arborization of serotonergic axons. Administration of 5-HT<sub>1A</sub> receptor antagonists, antibodies to S-100 $\beta$ , or agents that deplete serotonin produces similar losses of dendrites, spines,

and/or synapses in adult and developing animals—effects that are blocked by administration of 5-HT<sub>1A</sub> receptor agonists or SSRIs. These observations have led to the hypothesis that a reduction of 5-HT<sub>1A</sub> receptor function may play an important role in mood disorders that are known to be associated with glial reductions ([Manji et al. 2001](#)). The use of conditional knockouts of the 5-HT<sub>1A</sub> receptor, in which gene expression is altered only in particular anatomical regions and/or during particular times, has illustrated the caution necessary in attributing complex behaviors to simple “too much” or “too little” neurotransmitter or receptor hypotheses. One report used a knockout/rescue approach with regional and temporal specificity to show that the anxiety-related effect of the 5-HT<sub>1A</sub> receptor knockout was actually developmental. Specifically, expression limited to the hippocampus and cortex during early postnatal development was sufficient to counteract the anxious phenotype of the mutant, even though the receptor was still absent in adulthood ([Gross et al. 2002](#)). As is discussed in the chapters on antidepressants (see [Chapters 8–23](#)), there is interest in the observation that antidepressants enhance hippocampal neurogenesis ([Duman 2002](#); [Malberg et al. 2000](#)). It is noteworthy that data suggest that 5-HT<sub>1A</sub> receptor activation is required for SSRI-induced hippocampal neurogenesis in mice ([Jacobs et al. 2000](#)). Altering serotonin levels with the SSRI fluoxetine does not affect division of stem cells in the dentate gyrus, but rather increases symmetric divisions of an early progenitor cell class that exists after stem-cell division ([Encinas et al. 2006](#)).

5-HT<sub>1A</sub> receptors are now known to use a variety of signaling mechanisms to bring about their effects in distinct

brain areas. Thus, somatodendritic 5-HT<sub>1A</sub> receptors appear to inhibit the firing of serotonergic neurons by opening a K<sup>+</sup> channel through a pertussis toxin-sensitive G protein (likely G<sub>o</sub>, discussed later in the section on G proteins) ([Andrade et al. 1986](#)), as well as by reducing cAMP levels. Postsynaptic 5-HT<sub>1A</sub> receptors appear to exert many of their effects by inhibiting adenylyl cyclase via G<sub>i</sub> ([De Vivo and Maayani 1990](#)) but also have been found to potentiate the activity of certain adenylyl cyclases ([Bourne and Nicoll 1993](#)) and to stimulate inositol-1,4,5-triphosphate (IP<sub>3</sub>) production and activate PKC ([Liu and Albert 1991](#)). Structurally, the 5-HT<sub>1A</sub> receptors are more related to D<sub>2</sub> receptors than to other serotonin receptors ([Squire 2013](#)). Functional polymorphisms in the promotor of 5-HT<sub>1A</sub> receptors influencing 5-HT<sub>1A</sub> receptor expression did not lead to changes in binding of 5-HT<sub>1A</sub> receptor antagonists in healthy subjects based on two PET studies, suggesting that there are compensatory mechanisms in the brains of healthy living human subjects ([Bortolato et al. 2013](#); [David et al. 2005](#); [Lothe et al. 2010](#)). PET studies also reported that 5-HT<sub>1A</sub> receptors decrease with advancing age in men, which may potentially explain the increased risk of suicide in this population ([Moses-Kolko et al. 2011](#)). A functional promoter polymorphism, rs6295, for which the G allele causes decreased transcription of 5-HT<sub>1A</sub>, may have a role in increasing risk for depression and suicide, because it is overrepresented in patients with depression, although the mechanism is not clear, because postmortem brain samples from depressed individuals who committed suicide showed more equal expression of the G allele with the C allele ([Donaldson et al. 2016](#); [Savitz et al. 2009](#)). Buspirone

is a 5-HT<sub>1A</sub> receptor agonist indicated for treating generalized anxiety disorder (Nestler et al. 2015).

5-HT<sub>1D</sub> receptors are virtually absent in rodents but have been detected in guinea pigs and humans (Bruinvels et al. 1993). On the basis of an approximately 74% sequence homology, it has been proposed that 5-HT<sub>1B</sub> receptors are the rodent homologue of 5-HT<sub>1D</sub> receptors (Saxena et al. 1998). Furthermore, the distribution of the 5-HT<sub>1D</sub> receptors in guinea pigs and humans is approximately equivalent to that of the 5-HT<sub>1B</sub> receptors in rats (Bruinvels et al. 1993). Both 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors have been proposed to represent the major nerve terminal autoreceptors regulating the amount of serotonin released per nerve impulse (Piñeyro and Blier 1999) (see Figure 2-3B). Like 5-HT<sub>1A</sub> receptors, 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors inhibit cAMP formation and stimulate IP<sub>3</sub> production and activate PKC (Schoeffer and Bobirnac 1995). This appears to be the case for many receptors coupled to G<sub>i</sub> and G<sub>o</sub> (Table 2-1). The  $\alpha$  subunits of the G protein ( $\alpha_i$  and  $\alpha_o$ ) inhibit adenylyl cyclase and regulate ion channels, respectively, whereas the  $\beta\gamma$  subunits activate PLC isozymes to stimulate IP<sub>3</sub> production and activate PKC. Examples of 5-HT<sub>1B/1D</sub> receptor agonists include the triptan family of medications used to treat migraines, which are incidentally contraindicated in patients who have comorbid coronary artery disease because of the presence of 5-HT<sub>1B</sub> receptors causing constriction of coronary arteries (Lambert 2005; Nestler et al. 2015). 5-HT<sub>1B</sub> receptor agonists have shown promise for decreasing reactive aggression and alcohol intake in animal models, but human polymorphism studies searching for a relationship between *HTR1B*

polymorphisms and aggression or suicide risk have yielded inconsistent results ([Bortolato et al. 2013](#)).

The 5-HT<sub>1C</sub> receptors have structural and transductional similarities to the 5-HT<sub>2</sub> receptor class ([Hoyer et al. 1986](#)).

**5-HT<sub>2</sub> receptors.** The three subtypes of 5-HT<sub>2</sub> receptors are 5-HT<sub>2A</sub>, 5-HT<sub>2B</sub>, and 5-HT<sub>2C</sub>. The highest level of 5-HT<sub>2A</sub> binding sites and mRNA for these receptors exists in the cortex, and these receptors have been implicated in the psychotomimetic effects of agents such as lysergic acid diethylamide, as reviewed by [Aghajanian and Marek \(1999\)](#). In addition, lesioning serotonin neurons with 5,7-DHT does not reduce the 5-HT<sub>2</sub> receptor density reported in brain regions ([Hoyer et al. 1986](#)), indicating that these receptors are primarily (if not exclusively) postsynaptic. Autoradiography performed with the potent and selective radioligand [<sup>3</sup>H]MDL 100,907 has localized 5-HT<sub>2A</sub> receptors to many similar brain regions in the rat and primate brain ([López-Giménez et al. 1997](#)). Hallucinogenesis is likely a result of cortical 5-HT<sub>2A</sub> receptor activation, because experiments in mice expressing 5-HT<sub>2A</sub> receptors in the cortex only incur receptor signaling and behavior changes to hallucinogenic drugs similar to that of genetically unaltered mice ([González-Maeso et al. 2007](#)). Competition studies with other radioligands ([Westphal and Sanders-Bush 1994](#)) and their mRNA distribution indicate that 5-HT<sub>2C</sub> receptors are considerably widespread throughout the CNS, with the highest density in the choroid plexus ([Hoffman and Mezey 1989](#)). 5-HT<sub>2B</sub> receptors are detected sparingly in the brain and are more prominently located in the fundus, gut, kidney, lungs, and heart ([Hoyer et al. 1986](#)).

Evidence from animal experiments in which cortical 5-HT<sub>2A</sub> receptors are disrupted indicates a specific role of

these receptors in modulation of conflict anxiety without affecting fear conditioning and depression-like behaviors (Weisstaub et al. 2006). Furthermore, chronic administration of many antidepressants downregulates 5-HT<sub>2</sub> receptors, suggesting that this effect may be important for their efficacy (Scott and Crews 1986). However, chronic electroconvulsive shock appears to upregulate 5-HT<sub>2</sub> expression, precluding a simple mechanism for antidepressant efficacy. The obesity seen in 5-HT<sub>2C</sub> knockout animals suggests that in addition to histamine receptor blockade, 5-HT<sub>2C</sub> receptor blockade may play a role in the weight gain observed with certain psychotropic agents; this is an area of considerable research. In keeping, evidence suggests that the weight gain “orexigenic” properties of atypical antipsychotics are likely due to potent activation of hypothalamic AMP-kinase through histamine type 1 (H<sub>1</sub>) receptors (Kim et al. 2007). Aggressive and impulsive behaviors are also linked to the serotonin system, in which a neuropeptide Y (NPY) and serotonin interaction from studies in NPY knockout mice detected circuits responsible for aggressive behavior linked to feeding (Emeson and Morabito 2005). The regulation of 5-HT<sub>2</sub> receptors is intriguing, as not only is it important in psychiatric disorders and therapeutic benefit, but also both agonists and antagonists appear to cause an internalization of the receptor. Moreover, data suggest that mRNA editing may play an important role in regulating the levels and activity of this receptor subtype (Niswender et al. 1998). All of the 5-HT<sub>2</sub> receptor subtypes are linked to the phosphoinositide signaling system, and their activation produces IP<sub>3</sub> and diacylglycerol (DAG), via PLC activation (Conn and Sanders-Bush 1987) (see Figure 2-3B).

A pharmacogenetic study searched for genetic predictors of treatment outcome in 1,953 patients with MDD who received the antidepressant citalopram in the Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) study and were prospectively assessed ([McMahon et al. 2006](#)). In a split-sample design, a selection of 68 candidate genes was genotyped with 768 single-nucleotide-polymorphism markers chosen to detect common genetic variation. A significant and reproducible association was found between treatment outcome and a marker in *HTR2A* ( $P=1\times 10^{-6}$  to  $3.7\times 10^{-5}$  in the total sample). The “A” allele (associated with better outcome) was six times more frequent in white than in black participants, for whom treatment was also less effective in this sample ([McMahon et al. 2006](#)). The A allele thus may contribute to racial differences in outcomes of antidepressant treatment. Taken together with prior neurobiological findings, these genetic data make a compelling case for a key role of *HTR2A* in the mechanism of antidepressant action.

A leading hypothesis for the mechanism of action of atypical antipsychotic agents suggests that the ratio of D<sub>2</sub>-to-5-HT<sub>2</sub> blockade confers “atypicality” properties of many currently available antipsychotic agents ([Meltzer 2002](#)). Several antidepressants (e.g., mianserin, mirtazapine) and atypical antipsychotics (e.g., clozapine, risperidone, olanzapine) are antagonists of 5-HT<sub>2A</sub> receptors, raising the possibility that blockade of 5-HT<sub>2</sub> receptors may play an important role in the therapeutic efficacy of these agents ([Nestler et al. 2015](#)). Studies comparing the various compounds and the state of 5-HT<sub>2A/2C</sub> receptors based on psychiatric phenotype would be enhanced by the development of a highly specific PET ligand, [<sup>18</sup>F]FECIMBI-

36, which was confirmed in postmortem human brain tissue sections to bind at high levels to the prefrontal cortex (PFC), temporal cortex, and hippocampus for 5-HT<sub>2A</sub> receptors and to the choroid plexus for 5-HT<sub>2C</sub> receptors (Prabhakaran et al. 2015).

5-HT<sub>2C</sub> receptors are expressed on pro-opiomelanocortin (POMC) neurons of the arcuate nucleus of the hypothalamus (Nestler et al. 2015). The selective 5-HT<sub>2C</sub> receptor agonist lorcaserin is used for the treatment of obesity (Nestler et al. 2015). Many second-generation antipsychotic drugs cause weight gain through 5-HT<sub>2C</sub> receptor antagonism (Nestler et al. 2015).

**5-HT<sub>3-7</sub> receptors.** Unlike the other serotonin receptors, 5-HT<sub>3</sub> receptors are ligand-gated ion channels capable of mediating fast synaptic responses, although the opening of the channel is relatively slower compared with other ligand-gated ion channels (see Figure 2-3B) (Squire 2013; Yun and Rhim 2011). The *cis-trans* isomerization and molecular rearrangement at proline 8 is the structural mechanism that opens the 5-HT<sub>3</sub> receptor protein pore (Lummis et al. 2005). 5-HT<sub>3</sub> receptors are present in multiple brain areas, including the hippocampus, dorsal motor nucleus of the solitary tract, and area postrema (Laporte et al. 1992). The 5-HT<sub>3</sub> receptor, located mostly in the peripheral nervous system, is effectively modulated by a variety of compounds, such as alcohols and anesthetics, and antagonists of this receptor are used as effective antiemetics in patients who are undergoing chemotherapy (e.g., ondansetron) (Squire 2013).

5-HT<sub>4</sub>, 5-HT<sub>6</sub>, and 5-HT<sub>7</sub> are GPCRs that are preferentially coupled to G<sub>s</sub> and activate adenylyl cyclases

(see [Figure 2-3B](#)). 5-HT<sub>4</sub> receptors are able to modulate the release of monoamines and GABA in the brain, appear to improve memory and learning in mice, and mediate pituitary prolactin release in the presence of estrogen ([Darcet et al. 2016](#); [Papageorgiou and Denef 2007](#)). 5-HT<sub>4</sub> receptor subtypes include 5-HT<sub>4A</sub>, 5-HT<sub>4B</sub>, 5-HT<sub>4C</sub>, 5-HT<sub>4D</sub>, 5-HT<sub>4E</sub>, 5-HT<sub>4F</sub>, 5-HT<sub>4G</sub>, 5-HT<sub>4H</sub>, and 5-HT<sub>4HB</sub> ([Yun and Rhim 2011](#)). 5-HT<sub>5</sub> receptors are located in the hypothalamus, hippocampus, corpus callosum, fibra, cerebral ventricles, and glia ([Hoyer et al. 2002](#)). The 5-HT<sub>5A</sub> receptor is negatively coupled to adenylyl cyclase, whereas the 5-HT<sub>5B</sub> receptor is not functional because of stop codons ([Grailhe et al. 2001](#)). 5-HT<sub>6</sub> receptors are located in the striatum, amygdala, nucleus accumbens, hippocampus, cortex, and olfactory tubercle ([Hoyer et al. 2002](#)). Of interest, many antipsychotic agents and antidepressants are high-affinity antagonists of 5-HT<sub>6</sub> and 5-HT<sub>7</sub> receptors, and 5-HT<sub>6</sub> receptor antagonism is being specifically investigated for its ability to improve cognition in patients with Alzheimer's disease ([Parker et al. 2015](#); [Roth et al. 1994](#); [Yun and Rhim 2011](#)). 5-HT<sub>7</sub> receptors, made up of subtypes 5-HT<sub>7A</sub>, 5-HT<sub>7B</sub>, 5-HT<sub>7C</sub>, and 5-HT<sub>7D</sub>, have been localized to the cerebral cortex, medial thalamic nuclei, substantia nigra, central gray, and dorsal raphe nucleus ([Hoyer et al. 2002](#); [Yun and Rhim 2011](#)). Chronic treatment with antidepressants downregulates 5-HT<sub>7</sub> receptors, whereas acute stress has been reported to increase 5-HT<sub>7</sub> expression ([Sleight et al. 1995](#); [Yau et al. 2001](#)). Lurasidone and vortioxetine, agents used to treat schizophrenia and depression, respectively, are also nonselective 5-HT<sub>7</sub> receptor antagonists that work through increased AMPA-

mediated neurotransmission ([Andreetta et al. 2016](#); [Fountoulakis et al. 2015](#); [Sanchez et al. 2015](#)).

In the future, the subtle differences between the different serotonin receptors and their subtypes will be elucidated as specific PET ligands, genotype-phenotype correlations, and receptor-selective medications are developed ([Kumar and Mann 2014](#)).

## Dopaminergic System

Dopamine was originally thought to be simply a precursor of norepinephrine and epinephrine synthesis, but the demonstration that its distribution in the brain was quite distinct from that of norepinephrine led to extensive research establishing its role as a critical, unique neurotransmitter. Dopamine synthesis requires transport of the amino acid L-tyrosine across the blood-brain barrier and into the cell. Once tyrosine enters the neuron, the rate-limiting step for dopamine synthesis is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase; L-dopa is readily converted to dopamine and, hence, is used as a precursor strategy to correct a dopamine deficiency in the treatment of Parkinson's disease ([Figure 2-4B](#)). The activity of tyrosine hydroxylase can be regulated by many factors, including the activity of catecholamine neurons; furthermore, catecholamines function as end-product inhibitors of tyrosine hydroxylase by competing with a tetrahydrobiopterin cofactor ([Cooper et al. 2003](#)).

In contrast to the widespread serotonin and norepinephrine projections, dopamine neurons form more discrete circuits, with the nigrostriatal, mesolimbic,

tuberoinfundibular, and tuberohypophysial pathways constituting the major CNS dopaminergic circuits ([Figure 2-4A](#)). The nigrostriatal circuit is composed of dopamine neurons from the mesencephalic reticular formation (region A8) and the pars compacta region of the substantia nigra (region A9) of the mesencephalon. These neurons give rise to axons that travel via the medial forebrain bundle to innervate the caudate nucleus and putamen ([Andén et al. 1964](#); [Ungerstedt 1971](#)). The dopamine neurons that make up the nigrostriatal circuit have been assumed to be critical for maintaining normal motor control, because destruction of these neurons is associated with Parkinson's disease; however, it is now clear that these projections subserve a variety of additional functions. For instance, evidence from human brain imaging studies indicates that drugs that modulate striatal dopamine receptor activation correlate with the subject's ability to choose gradations of rewarding actions during instrumental learning tasks. This further implies that the dopamine reward pathway in the brain is likely convergent on many discrete brain circuits and neurotransmitter alterations and shows that striatal activity can also account for how the human brain proceeds toward making future decisions based on reward prediction ([Pessiglione et al. 2006](#)).

The mesolimbic dopamine circuit consists of dopamine neurons located in the midbrain just medial to the A9 cells in an area termed the *ventral tegmental area* (VTA) ([Cooper et al. 2003](#); [Nestler et al. 2015](#); [Squire 2013](#)). This circuit shares some similarities to the nigrostriatal circuit in that it is a parallel circuit consisting of axons that make up the medial forebrain bundle. However, these axons ascend through the lateral hypothalamus and project to the nucleus accumbens; olfactory tubercle; bed nucleus of the

stria terminalis; lateral septum; and frontal, cingulate, and entorhinal regions of the cerebral cortex ([Cooper et al. 2003](#)). This circuit innervates many limbic structures known to play critical roles in motivational, motor, and reward pathways and has therefore been implicated in a variety of clinical conditions, including psychosis and drug abuse ([Cooper et al. 2003](#)). Data also suggest a potential role of dopamine—and, in particular, mesolimbic pathways—in the pathophysiology of bipolar mania, as well as bipolar and unipolar depression ([Beaulieu et al. 2004](#); [Dunlop and Nemeroff 2007](#); [Goodwin et al. 2007](#); [Roybal et al. 2007](#)). It is perhaps surprising that the role of the dopaminergic system in the pathophysiology of mood disorders has not received greater study, because it represents a prime candidate on several theoretical grounds. The motoric changes in bipolar disorder are perhaps the most defining characteristics of the illness, ranging from near catatonic immobility to the hyperactivity of manic states. Similarly, loss of motivation is one of the central features of depression, whereas anhedonia and “hyperhedonic states” are among the most defining characteristics of bipolar depression and mania, respectively. In this context, it is noteworthy that the midbrain dopaminergic system is known to play a critical role in regulating not only motoric activity but also motivational and reward circuits. It is clear that motivation and motor function are closely linked and that motivational variables can influence motor output both qualitatively and quantitatively. Furthermore, considerable evidence indicates that the mesolimbic dopaminergic pathway plays a crucial role in the selection and orchestration of goal-directed behaviors, particularly those elicited by incentive stimuli ([Goodwin et al. 2007](#)).

The firing pattern of mesolimbic dopamine neurons appears to be an important regulatory mechanism; thus, in rats, electrical or glutamatergic stimulation of medial PFC elicits a burst firing pattern of dopaminergic cells in the VTA and increases dopamine release in the nucleus accumbens (Murase et al. 1993; Taber and Fibiger 1993). The burst firing of dopamine cell activity elicits more terminal dopamine release per action potential than the nonbursting, pacemaker firing pattern (Roth et al. 1987). The phasic, burst firing of dopamine neurons and accompanying rise in dopamine release normally occur in response to primary rewards (until they become fully predicted) and reward-predicting stimuli. Such a role also has been postulated to provide a neural mechanism by which PFC dysfunction could alter hedonic perceptions and motivated behavior in mood disorders (Drevets et al. 2002). Studies indicate that the amygdala has importance in the learning of new cocaine drug-seeking responses and its habit-forming properties (Lee et al. 2005). The supraphysiological levels of dopamine induced by cocaine and other drugs of abuse lead to powerful reinforcement of drug-seeking behavior, by co-opting the dopamine reward circuit of the brain, as reviewed elsewhere (Volkow and Morales 2015).

## Dopamine Transporters

As with serotonin, the dopamine signal in the synaptic cleft is terminated primarily by reuptake into the presynaptic terminal. The DAT comprises 12 transmembrane domains and is located somatodendritically as well as on dopamine nerve terminals (see Figure 2-4B). Like other monoamine transporters, the DAT functions as a Na<sup>+</sup>/K<sup>+</sup> pump to clear dopamine from the synaptic cleft on its release. However,

data suggest that many drugs of abuse are capable of altering the function of these transporters. Thus, the amphetamines are thought to mediate their effects, in part, by reversing the direction of the transporter so that it *releases* dopamine. Cocaine is capable of blocking the reuptake of DAT, leading to an increase in dopamine in the synaptic cleft. Of interest, altered neuronal long-term potentiation in the VTA in response to chronic cocaine exposure has been linked to drug-associated memory and likely contributes to the powerful addictive potential of this drug of abuse ([Liu et al. 2005](#)). Dopamine in the medial frontal cortex is taken up predominantly by the norepinephrine transporter, which goes against the dogma of transporters being able to selectively take up only their respective neurotransmitter. Furthermore, this provides a mechanism by which norepinephrine reuptake-inhibiting antidepressants also may increase synaptic levels of dopamine in the frontal cortex, an effect that may be therapeutically very important. Interestingly, a meta-analysis of single photon emission computed tomography (SPECT) scans examining the DAT gene *SLC6A3* variable-number tandem repeat (VNTR) polymorphism did not find significant changes in the levels of the dopamine transporters in the brains of patients with schizophrenia, attention-deficit/hyperactivity disorder (ADHD), and even Parkinson's disease ([Costa et al. 2011](#)). However, another DAT polymorphism of note, a VNTR in the nontranslated 3' end of exon 15, causes a 25% decreased density of DAT in humans with a VNTR of 9 repeats instead of the more common 10 repeats ([Lacerda-Pinheiro et al. 2014](#)). SPECT scanning of the brain with the presynaptic DAT radioligand is now being used to distinguish Parkinson's disease syndromes from other causes of parkinsonism such as

antipsychotic-induced parkinsonism, the latter of which does not show a deficit in DAT binding in the caudate and putamen ([Tatsch and Poepperl 2013](#)).

In patients with MDD and bipolar disorder, SPECT studies showed that DAT availability is higher—and, by inference, synaptic dopamine is lower—in patients with depression ([Camardese et al. 2014a, 2014b](#)). PET studies identified decreased binding potential of the DAT PET ligand to the dopamine transporter in the striatum in MDD patients and more specifically in the caudate in bipolar patients ([Anand et al. 2011](#); [Meyer et al. 2001](#); [Savitz and Drevets 2013](#)). Postmortem studies in patients with MDD showed lower DAT levels in the amygdala and higher D<sub>2</sub> and D<sub>3</sub> receptor levels (no change in D<sub>1</sub> receptors), consistent with similar observations in rats with dopamine depletion ([Klimek et al. 2002](#)).

To treat refractory depression, the new triple transporter reuptake inhibitor compound BMS-820836, reported by PET studies to specifically inhibit monoamine transporters DAT, SERT, and NET, was developed for the goal of increasing synaptic levels of the respective monoamines dopamine, serotonin, and norepinephrine and thereby decreasing depressive symptoms ([Risinger et al. 2014](#)). Moderate to severe MDD or atypical MDD (with reversed neurovegetative symptoms) was found by PET studies to be associated with higher levels of MAO-A, an enzyme that catabolizes and thus decreases synaptic dopamine, serotonin, and norepinephrine, presumably increasing depressive symptoms ([Chiuccariello et al. 2014](#)). Classic MAOIs increase all three monoamines in the synapse by blocking the catabolizing enzyme MAO (both A and B enzyme subtypes).

Bupropion is widely believed to increase synaptic dopamine by blocking the DAT-mediated reuptake, but a PET study showed that it has at most only 22% occupancy of the DAT ([Meyer et al. 2002](#)). Given the observation of a decreased binding potential of 15% of DAT in patients with MDD, it remains unknown whether bupropion occupies the same binding site on DAT as the PET ligand, whether 22% occupancy of DAT is sufficient for bupropion to work (as compared with 80% binding to SERT for SSRIs), and whether bupropion works by another uncharacterized mechanism to achieve its antidepressant properties ([Meyer et al. 2001, 2002](#)).

## Dopaminergic Receptors

The existence of two subtypes of dopamine receptors, D<sub>1</sub> and D<sub>2</sub>, was initially established with classic pharmacological techniques in the 1970s ([Stoof and Kebabian 1984](#)). Subsequent molecular biological studies have shown that the D<sub>1</sub> family contains both the D<sub>1</sub> and the D<sub>5</sub> receptors, whereas the D<sub>2</sub> family contains the D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub> receptors ([Cooper et al. 2003](#)). D<sub>1</sub> receptor family members were originally defined solely on the ability to stimulate adenylyl cyclase, whereas the D<sub>2</sub> family inhibited the enzyme. Interestingly, dopamine receptors complexed with subunits from other subclasses of dopamine receptors within a receptor family are able to form distinct hetero-oligomeric receptors also termed *kissing cousin receptors*. Notably, hetero-oligomeric D<sub>1</sub>-D<sub>2</sub> receptor complexes in the brain require binding to active sites of both receptor subtypes to induce activation of the hetero-oligomeric receptor complex. These receptors have been shown to use traditional D<sub>1</sub> receptor intracellular signaling components

of  $G_{q/11}$  and  $Ca^{2+}$ /calmodulin-dependent protein kinase II (CaMKII) second-messenger activation as seen in the nucleus accumbens ([Rashid et al. 2007](#)). This opens up possibilities for the brain to use different receptor subunit proportions to further fine-tune brain neurophysiology. Similar to the *DAT* exon 15 VNTR, the  $D_2$  dopamine receptor gene (*DRD2*) has a TaqIA polymorphism (allele A1+) in the 3' nontranslated region that reduces  $D_2$  receptor density ([Lacerda-Pinheiro et al. 2014](#)).

**$D_1$  and  $D_5$  receptors.** The  $D_1$  and  $D_5$  receptors stimulate adenylyl cyclase activity via the activation of  $G_s$  or  $G_{olf}$  (a G protein originally thought to be present exclusively in olfactory tissue but now known to be abundantly present in limbic areas) (see [Figure 2-4B](#)). Other second-messenger pathways also have been reported to be activated by  $D_1$  receptors, an effect that may play a role in the reported  $D_1$ - $D_2$  cross-talk ([Clark and White 1987](#)). The frontal cortex contains almost exclusively  $D_1$  receptors ([Clark and White 1987](#)), suggesting that this receptor may play an important role in higher cognitive function and perhaps in the actions of medications such as methylphenidate. A  $D_1/D_5$  receptor agonist, dihydrexidine, has been developed and tested for its ability to improve cognition and working memory in patients with schizophrenia but was prematurely terminated because of hypotension and potentially increased seizure risk ([Arnsten et al. 2017](#)). Although the  $D_5$  receptor is a neuron-specific receptor located primarily in limbic areas of the brain, no compounds have been developed so far that pharmacologically distinguish it from the homologous  $D_1$  receptor ([Arnsten et al. 2017](#)). Drugs

such as cocaine and methylphenidate cause peak dopamine activation of D<sub>1</sub> receptors on striatal GABAergic medium spiny neurons, which plays a key role in the direct striatal pathway mediating expectations of reward ([Volkow and Morales 2015](#)).

**D<sub>2</sub> receptors.** Four types of D<sub>2</sub> receptors have been identified: two subtypes of D<sub>2</sub> receptors (the short and long splice variants, D<sub>2S</sub> and D<sub>2L</sub>, respectively) and D<sub>3</sub> and D<sub>4</sub> receptors. Although a seemingly identical pharmacological profile for these receptors exists, there are undoubtedly physiological differences between the two subtypes. D<sub>2</sub> receptors mediate their cellular effects via the G<sub>i</sub>/G<sub>o</sub> proteins and thereby several effectors (see [Figure 2-4B](#)). In addition to the well-characterized inhibition of adenylyl cyclase, D<sub>2</sub> receptors in different brain areas also regulate PLC, bring changes in K<sup>+</sup> and Ca<sup>2+</sup> currents, and possibly regulate phospholipase A<sub>2</sub>. D<sub>2</sub> receptors are located on cell bodies and nerve terminals of dopamine neurons and function as autoreceptors. Thus, activation of somatodendritic D<sub>2</sub> receptors reduces dopamine neuron firing activity, likely via the opening of K<sup>+</sup> channels, whereas activation of nerve-terminal D<sub>2</sub> autoreceptors reduces the amount of dopamine released per nerve impulse, in large part by closing voltage-gated Ca<sup>2+</sup> channels. As discussed extensively elsewhere in this volume (see [Chapter 24, “Classic Antipsychotic Medications,” by Nasrallah and Tandon](#)), D<sub>2</sub> receptors have long been implicated in the pathophysiology and treatment of schizophrenia. In one study, transgenic mice overexpressing D<sub>2</sub> receptors in the striatum had many

phenotypic hallmarks of schizophrenia ([Kellendonk et al. 2006](#)). However, the potential role of D<sub>2</sub> receptors in contributing to depression is a comparatively more recent recognition, confirmed by the observation that D<sub>2</sub> receptor binding is increased by PET ligand [<sup>11</sup>C]raclopride in the putamen of patients with MDD and psychomotor retardation, reflecting decreased dopamine levels in the synapse ([Meyer et al. 2006](#)).

The typical antipsychotics are generally defined by their high-affinity antagonism or blockade of the D<sub>2</sub> receptor, which substantially prevents synaptic dopamine from activating the postsynaptic receptor but also has a significant risk for extrapyramidal side effects (EPS) such as dystonia and akathisia in the short term and parkinsonism and tardive dyskinesia in the longer term (see [Figure 2-4B](#)). Medications with high anticholinergic properties, such as diphenhydramine and benztropine, are frequently used to avoid development of EPS, but tardive dyskinesia can develop nevertheless after many years of antipsychotic exposure. Cocaine and methylphenidate stimulation of D<sub>2</sub> receptors in the indirect, inhibitory striatal pathway, which mediates punishment, leads to sustained motivation to procure these drugs in the future ([Volkow and Morales 2015](#)).

**D<sub>3</sub> receptors.** D<sub>3</sub> receptors possess a different anatomical distribution than D<sub>2</sub> receptors and, because of their preferential limbic expression, have been postulated to represent an important target for antipsychotic drugs. Numerous studies have investigated the position association of a polymorphism in the coding sequence of the D<sub>3</sub> receptor with schizophrenia, with equivocal results. It

has been suggested that brain-derived neurotrophic factor (BDNF) may regulate behavioral sensitization via its effects on D<sub>3</sub> receptor expression ([Guillin et al. 2001](#)). Cariprazine, an antipsychotic with possible efficacy in treating acute mania, has antagonist/partial agonist binding to D<sub>2</sub> and D<sub>3</sub> receptors, with a much higher affinity for D<sub>3</sub> receptors compared with other antipsychotics, but it still has significant D<sub>2</sub>-related EPS ([Altinbaş et al. 2013](#)). Bupropion, a 5-HT<sub>1a</sub> receptor partial agonist, also has D<sub>3</sub>/D<sub>4</sub> receptor antagonist activity, so it is being considered for treating methamphetamine and cocaine dependence, given the observation of increased brain D<sub>3</sub> receptors by PET studies in addicted individuals and the attenuation of self-administration in animals given D<sub>3</sub> receptor antagonists ([Paterson et al. 2014](#)).

**D<sub>4</sub> receptors.** The D<sub>4</sub> receptor has received much interest in psychopharmacological research because of the fact that clozapine has a high affinity for this receptor. More selective D<sub>4</sub> antagonists are being explored as adjunctive agents in the treatment of schizophrenia. Furthermore, considerable attention has focused on the possibility that genetic D<sub>4</sub> variants may be associated with thrill-seeking behavior ([Zuckerman 1985](#)), ADHD ([Roman et al. 2001](#)), and responsiveness to clozapine ([Van Tol et al. 1992](#)). A potent, selective antagonist of the D<sub>4</sub> receptor called ML398 has been developed that is still being investigated ([Berry et al. 2014](#)).

## Noradrenergic System

Named *sympathine* because it was initially encountered as being released by sympathetic nerve terminals, the molecule was later given the name *norepinephrine* after meeting the criteria for a neurotransmitter in the CNS (Cooper et al. 2003). Norepinephrine is produced from the amino acid precursor L-tyrosine found in neurons in the brain, chromaffin cells, sympathetic nerves, and ganglia. The enzyme dopamine  $\beta$ -hydroxylase converts dopamine to norepinephrine, and as is the case for dopamine synthesis, tyrosine hydroxylase is the rate-limiting enzyme for norepinephrine synthesis (Figure 2-5B). The dietary depletion of tyrosine and  $\alpha$ -methyl-*p*-tyrosine (a tyrosine hydroxylase inhibitor) has played an important part in efforts aimed at delineating the role of catecholamines in the pathophysiology and treatment of mood and anxiety disorders (Coupland et al. 2001; McCann et al. 1995).

## FIGURE 2-5. The noradrenergic system.

*See Plate 8 to view this figure in color.*

This figure depicts the noradrenergic projections throughout the brain **(A)** and the various regulatory processes involved in norepinephrine (NE) neurotransmission **(B)**. NE neurons innervate nearly all parts of the neuroaxis, with neurons in the locus coeruleus being responsible for most of the NE in the brain (90% of NE in the forebrain and 70% of total NE in the brain). The amino acid L-tyrosine is actively transported into presynaptic NE nerve terminals, where it is ultimately converted into NE. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase (TH).  $\alpha$ -Methyl-*p*-tyrosine (AMPT) is a competitive inhibitor of tyrosine hydroxylase and has been used to assess the impact of reduced catecholaminergic function in clinical studies. Aromatic amino acid decarboxylase (AADC) converts L-dopa to dopamine (DA). L-dopa then becomes decarboxylated by decarboxylase to form DA. DA is then taken up from the cytoplasm into vesicles, by vesicular monoamine transporters (VMATs), and hydroxylated by dopamine  $\beta$ -hydroxylase (DBH) in the presence of O<sub>2</sub> and ascorbate to form NE. Normetanephrine (NM), which is formed by the action of catechol-*O*-methyltransferase (COMT) on NE, can be further metabolized by monoamine oxidase (MAO) and aldehyde reductase to 3-methoxy-4-hydroxyphenylglycol (MHPG). Reserpine causes a depletion of NE in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this hypertension). Once released from the presynaptic terminal, NE can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of NE neuron firing activity and release occurs through somatodendritic (not shown) and nerve-terminal  $\alpha_2$  adrenoreceptors, respectively. Yohimbine potentiates NE neuronal firing and NE release by blocking these  $\alpha_2$  adrenoreceptors,

thereby disinhibiting these neurons from a negative feedback influence. Conversely, clonidine attenuates NE neuron firing and release by activating these receptors. Idazoxan is a relatively selective  $\alpha_2$  adrenoreceptor antagonist primarily used for pharmacological purposes. The binding of NE to G protein receptors ( $G_o$ ,  $G_i$ , etc.) that are coupled to adenylyl cyclase (AC) and phospholipase C- $\beta$  (PLC- $\beta$ ) produces a cascade of second-messenger and cellular effects (see diagram and later sections of the text). NE has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron via NE transporters (NETs). Once inside the neuron, it can either be repackaged into vesicles for reuse or undergo enzymatic degradation. The selective NE reuptake inhibitor and antidepressant reboxetine and older-generation tricyclic antidepressant desipramine are able to interfere/block the reuptake of NE. On the other hand, amphetamine is able to facilitate NE release by altering NET function. Green spheres represent DA neurotransmitters; blue spheres represent NE neurotransmitters. cAMP=cyclic adenosine monophosphate; DAG=diacylglycerol; DOPA=dihydroxyphenylalanine;  $IP_3$ =inositol-1,4,5-triphosphate; NA=nucleus accumbens.

The mammalian CNS has seven norepinephrine cell groups, designated A1 through A7. In the brain stem, these are the lateral tegmental neurons (A5 and A7) and the locus coeruleus neurons (A6) ([Dahlström 1971](#)) (see [Figure 2-5B](#)). In general, the projections from A5 and A7 are more

restricted to brain stem areas and do not interact with those of A6. The term *locus coeruleus* (LC) was derived from the Greek because of its saddle shape and its “blueish color” (*caeruleum*). The LC is the most widely projecting CNS nucleus known (Foote et al. 1983), responsible for approximately 90% of the norepinephrine innervation of the forebrain and 70% of the total norepinephrine in the brain (Figure 2-5A). Indeed, the LC norepinephrine neurons, although small in number, constitute a diffuse system of projections to widespread brain areas via highly branched axons. The extensive efferent innervation suggests that the LC plays a modulatory and integrative role rather than a role in specific sensory or motor processing (Foote et al. 1983).

Several physiological roles have been ascribed to the LC, notably in the control of vigilance and the initiation of adaptive behavioral responses (Foote et al. 1983). Considerable data support the hypothesis that norepinephrine neurons in the LC constitute a CNS response or defense system, because the neurons are activated by “challenges” in both the behavioral/environmental and the physiological domains (Jacobs et al. 1991). Thus, various sensory stimuli are capable of increasing LC activity, but noxious or stressful stimuli are particularly potent in this regard. Moreover, considerable evidence also supports a role for LC norepinephrine neurons in the learning of aversively motivated tasks and in the conditioned response to stressful stimuli (Rasmussen and Jacobs 1986; Rasmussen et al. 1986), with obvious implications for a variety of psychiatric conditions (Gould et al. 2002; Szabo and Blier 2001). Indeed, tonic activation of the LC occurs preferentially in the response to stressful stimuli, in contrast to stimuli

limited to simply evoking activation or arousal ([Rasmussen and Jacobs 1986](#); [Rasmussen et al. 1986](#)). Preclinical studies have found increased sensitivity of the LC norepinephrine system in females compared with males, which may help explain the increased incidence of posttraumatic stress disorder (PTSD) and depression in human females ([Bangasser et al. 2016](#)). Of note, the LC also releases neuropeptides such as galanin, NPY, cocaine- and amphetamine-related transcript, and BDNF; galanin specifically co-localizes with norepinephrine in LC neurons as they project to the PFC, hippocampus, and VTA and mediate stress responses and addictive behaviors ([Weinshenker and Holmes 2016](#)). Increased norepinephrine and activation of the LC may be involved in both fear and anger responses, and excessive anger may be a “vent” for fear of the unexpected, as suggested in one review ([Gu et al. 2016](#)).

## **Norepinephrine Transporter**

NET, the first of the monoamine transporters to be cloned in humans, transports norepinephrine from the synaptic cleft back into the neuron ([Pacholczyk et al. 1991](#)). Like other monoamine transporters, the NET comprises 12 putative transmembrane domains, and autoradiography with various norepinephrine reuptake inhibitors has been used to determine the brain distribution of NET. A high level of NET is found in the LC, with moderate to high levels found in the dentate gyrus, raphe nuclei, and hippocampus ([Tejani-Butt and Ordway 1992](#); [Tejani-Butt et al. 1990](#)). This pattern of expression is consistent with the norepinephrine innervation to these structures. The NET is expressed mainly on norepinephrine terminals, as shown by a drastic reduction in labeling following norepinephrine destruction

with the neurotoxin 6-hydroxydopamine or *N*-(2-chloroethyl)-*N*-ethyl-2-bromobenzylamine (DSP-4) (Tejani-Butt and Ordway 1992; Tejani-Butt et al. 1990).

The NET is dependent on extracellular Na<sup>+</sup> to mediate norepinephrine reuptake and the effectiveness of norepinephrine reuptake inhibitors in inhibiting norepinephrine reuptake (Brüss et al. 1997, 1999; Harder and Bönisch 1985). The uptake of norepinephrine is chloride dependent, meaning that the electrogenic process of norepinephrine transport is Na<sup>+</sup> and Cl<sup>-</sup> driven (Harder and Bönisch 1985). In addition to the electrogenic process, the NET has properties of a channel-like pore, in that it can transport norepinephrine showing an infinite stoichiometry that can be blocked by cocaine and desipramine (Galli et al. 1995, 1996). Several studies suggest that the NET can be regulated by diverse stimuli, neuronal activity, and peptide hormones, as well as protein kinases. Indeed, studies have shown that all monoaminergic transporters (5-HTT, DAT, and NET) are rapidly regulated by direct or receptor-mediated activation of cellular kinases, particularly PKC (Bauman et al. 2000). PKC activation results in an activity-dependent transporter phosphorylation and sequestration. Protein phosphatase-1/2A (PP-1/PP-2A) inhibitors, such as okadaic acid and calyculin A, also promote monoaminergic transporter phosphorylation and functional downregulation (Bauman et al. 2000). These phenomena that occur beyond the receptor level may well be important in the long-term actions of psychotropic drugs known to regulate protein kinases (Chen et al. 1999; Manji and Lenox 1999). Given that norepinephrine neurons co-localize and release orexins, it is of interest that these neuropeptides have been implicated in sleep disorders and hypoglycemia through the glucose-sensing tandem membrane receptor K<sup>+</sup> channels

(K<sub>2P</sub> type) affecting coordinated arousal ([Scott et al. 2006](#)). It is also interesting that enkephalin, an endogenous opioid peptide, co-localizes with NET on the axon terminals of the basolateral amygdala, as indicated by transmission electron microscopy and immunohistochemistry ([Zhang and McDonald 2016](#)). The latest PET radiotracer developed for human brain NET showed high uptake in the LC as well as the raphe nucleus, red nucleus, and thalamus, which could aid in monitoring disease progression of various conditions with NET dysregulation, including Parkinson's disease, Alzheimer's disease, epilepsy, ADHD, depression, and anxiety ([Adhikarla et al. 2016](#)). Atomoxetine, a selective NET inhibitor and the first nonstimulant medication approved for the treatment of ADHD in humans, was found to occupy both the NET and the SERT at clinically relevant doses when tested in rhesus monkeys ([Ding et al. 2014](#)).

## Adrenergic Receptors

The  $\alpha$  and  $\beta$  catecholamine receptors were first discovered more than 50 years ago ([Ahlquist 1948](#)) and were later subdivided further into  $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$ ,  $\beta_2$ , and  $\beta_3$  adrenoreceptors—all of which are GPCRs—on the basis of molecular cloning and pharmacological and biochemical studies (see [Figure 2-5B](#)). The crystal structures of these receptors were subsequently solved, along with those of other GPCRs, as reviewed elsewhere ([Millar and Newton 2010](#)).

**$\alpha$  Receptors.** The three subtypes of  $\alpha_1$  receptors are denoted 1A, 1B, and 1D; they are all positively coupled to PLC and possibly phospholipase A<sub>2</sub> (see [Figure 2-5B](#)). The  $\alpha_2$  family comprises the 2A/D, 2B, and 2C subtypes, which

couple negatively to adenylyl cyclase and regulate  $K^+$  and  $Ca^{2+}$  channels (see [Figure 2-5B](#)). The 2A, 2B, and 2C adrenoceptors correspond to the human genes *ADRA2A*, *ADRA2B*, and *ADRA2C*, respectively. The bovine, guinea pig, rat, and mouse  $\alpha_{2D}$  adrenoceptor is thought to be a species homologue or variant of the human  $\alpha_{2A}$  adrenoceptor ([Bylund et al. 1994](#)) and is often referred to as  $\alpha_{2A/D}$ . The  $\alpha_2$  receptors represent autoreceptors for norepinephrine neurons, and blockade of these autoreceptors results in increased norepinephrine release—a biochemical effect that has been postulated to play a role in the mechanisms of action of selected antidepressants (e.g., mianserin, mirtazapine) and antipsychotics (e.g., clozapine). In the LC,  $\alpha_2$ -adrenergic receptors converge onto similar  $K^+$  channels as  $\mu$  opioid receptors, and this convergence has been postulated to represent a mechanism for the efficacy of clonidine (an  $\alpha_2$  agonist) in attenuating some of the physical symptoms of opioid withdrawal. In addition, clonidine and another  $\alpha_2$  receptor agonist, guanfacine, have both been approved as nonstimulant medications to treat ADHD ([Chan et al. 2016](#)). The  $\alpha_2$  receptor antagonist yohimbine, which robustly increases norepinephrine neuron firing and norepinephrine release, has been used as a provocative challenge in clinical studies of anxiety disorders and as an antidepressant-potentiating agent. Yohimbine also has been used to explore the role of  $\alpha_2$  adrenoceptors in modulating different types of pain in healthy humans given high-frequency electrical stimulation ([Vo and Drummond 2016](#)).

**$\beta$  Receptors.** The  $\beta$  receptor family comprises  $\beta_1$ ,  $\beta_2$ , and  $\beta_3$  adrenoceptors, which are all positively coupled to

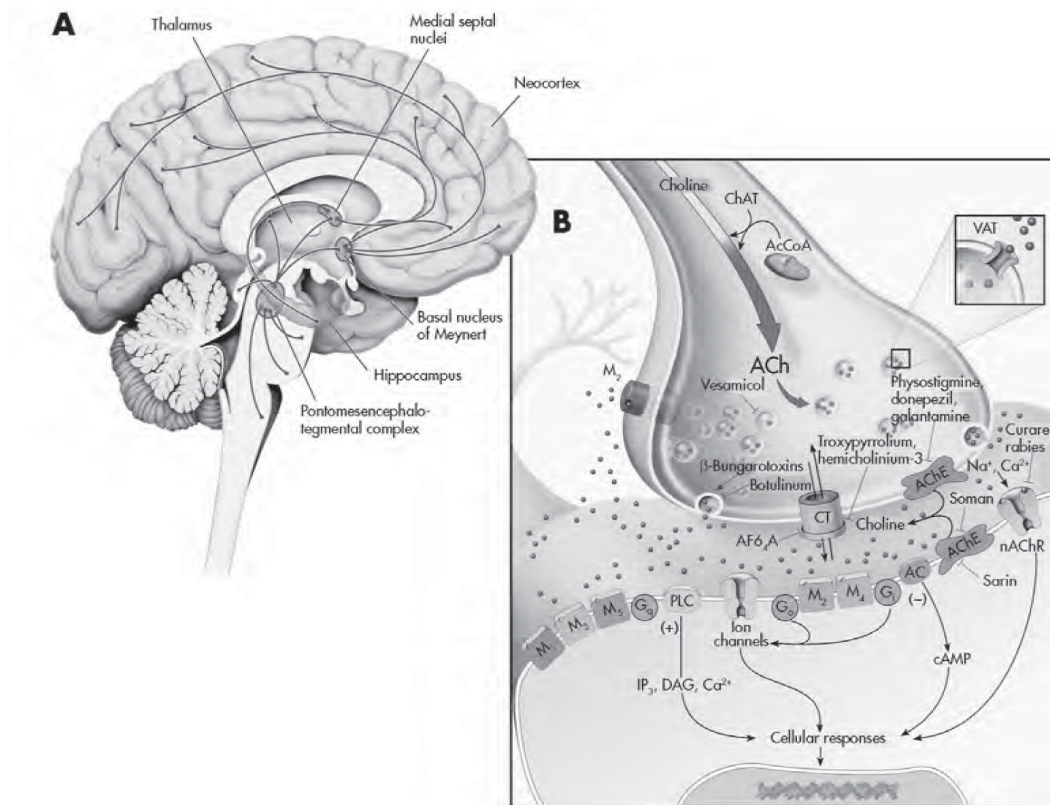

adenylyl cyclase ([Bylund et al. 1994](#)) (see [Figure 2-5B](#)). As is discussed in greater detail in the chapters on antidepressants (see [Chapters 8-23](#)), most effective antidepressants produce a downregulation/desensitization of  $\beta_1$  receptors in rat forebrain, leading to the suggestion that these effects may play a role in their therapeutic efficacy. Interestingly,  $\beta$  receptors also have been shown to play a role in regulating emotional memories, leading to the proposal that  $\beta$  antagonists may have utility in the treatment of PTSD ([Cahill et al. 1994](#); [Przybylski et al. 1999](#)). Propranolol, a combined  $\beta_1$ - $\beta_2$  receptor antagonist, has been used to try to prevent consolidation of traumatic memories in people who had just experienced trauma, such as rape victims or soldiers, but a meta-analysis suggested that it was not effective ([Argolo et al. 2015](#)). More recently, propranolol is being proposed to mitigate the development of intensive care unit-induced PTSD, which commonly stems from the trauma of hospitalization in an intensive care unit ([Gardner and Griffiths 2014](#)).  $\beta_3$  receptors are not believed to be present in the CNS but are abundantly expressed on brown adipose tissue (BAT), where they exert lipolytic and thermogenic effects. Not surprisingly, active researchers are attempting to develop selective  $\beta_3$  agonists for the treatment of obesity, and they are now called Class I BAT activators ([Mukherjee et al. 2016](#)).

## Cholinergic System

Acetylcholine (ACh) is the only major low-molecular-weight neurotransmitter substance that is not derived from an amino acid ([Kandel 2013](#)). ACh is synthesized from acetyl coenzyme A and choline in nerve terminals via the enzyme

choline acetyltransferase (ChAT). Choline is transported into the brain by uptake from the bloodstream and enters the neuron via both high-affinity and low-affinity transport processes ([Cooper et al. 2003](#)). In addition to the “standard” ChAT pathway, ACh can be synthesized by several possible mechanisms; the precise roles of these additional pathways and their physiological relevance in the CNS remain to be fully elucidated ([Cooper et al. 2003](#)). The highest activity of ChAT is observed in the interpeduncular nucleus, caudate nucleus, corneal epithelium, retina, and central spinal roots. In contrast to the other transmitters discussed thus far (which are most dependent on reuptake mechanisms), ACh has its signal terminated primarily by the enzyme ACh esterase, which degrades ACh ([Figure 2-6B](#)). Not surprisingly, therapeutic strategies to increase synaptic ACh levels (e.g., for the treatment of Alzheimer’s disease) have focused on inhibiting the activity of cholinesterases ([Nestler et al. 2015](#)).

**FIGURE 2-6.** The cholinergic system.

*See [Plate 9](#) to view this figure in color.*

This figure depicts the cholinergic pathways in the brain **(A)** and various regulatory processes involved in cholinergic neurotransmission **(B)**. Choline crosses the blood-brain barrier to enter the brain and is actively transported into cholinergic presynaptic terminals by an active uptake mechanism (requiring adenosine triphosphate [ATP]). This neurotransmitter is produced by a single enzymatic reaction in which acetyl coenzyme A (AcCoA) donates its acetyl group to choline by means of the enzyme choline acetyltransferase (ChAT). AcCoA is primarily synthesized in the mitochondria of neurons. Upon its formation, acetylcholine (ACh) is sequestered into secretory vesicles by vesicle ACh transporters (VATs), where it is stored. Vesamicol effectively blocks the transport of ACh into vesicles. An agent such as  $\beta$ -bungarotoxin or AF6<sub>4</sub>A is capable of increasing synaptic concentration of ACh by acting as a

releaser or a noncompetitive reuptake inhibitor, respectively. In turn, agents such as botulinum toxin are able to attenuate ACh release from nerve terminals. Once released from the presynaptic terminals, ACh can interact with a variety of presynaptic and postsynaptic receptors. In contrast to many other monoaminergic neurotransmitters, the ACh signal is terminated primarily by degradation by the enzyme acetylcholinesterase (AChE) rather than by reuptake. Interestingly, AChE is present on both presynaptic and postsynaptic membranes and can be inhibited by physostigmine (reversible) and soman (irreversible). Currently, AChE inhibitors such as donepezil and galantamine are the only classes of agents that are FDA approved for the treatment of Alzheimer's disease. ACh receptors are of two types: muscarinic (G protein-coupled) and nicotinic (ionotropic). Presynaptic regulation of ACh neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal M2 autoreceptors, respectively. The binding of ACh to G protein-coupled muscarinic receptors that are negatively coupled to adenylyl cyclase (AC) or coupled to phosphoinositol hydrolysis produces a cascade of second-messenger and cellular effects (see diagram). ACh also activates ionotropic nicotinic acetylcholine (nACh) receptors. ACh has its action terminated in the synapse through rapid degradation by AChE, which liberates free choline to be taken back into the presynaptic neuron through choline transporters (CTs). Once inside the neuron, it can be reused for the synthesis of ACh, can be repackaged into vesicles for reuse, or undergoes enzymatic degradation. There are some relatively new agents that selectively antagonize the muscarinic receptors, such as CI-1017 for M<sub>1</sub>, methoctramine for M<sub>2</sub>, 4-DAMP for M<sub>3</sub>, PD-102807 for M<sub>4</sub>, and scopolamine (hardly a new agent) for M<sub>5</sub> (although it also has affinity for the M<sub>3</sub> receptor). Nicotine receptors (or nACh receptors) are activated by nicotine and the specific alpha(4)beta(2\*) agonist metanicotine. Mecamylamine is an ACh receptor antagonist. cAMP=cyclic adenosine monophosphate;

In brief, cholinergic neurons can act as local circuit neurons (interneurons) and are found in the caudate, putamen, nucleus accumbens, olfactory tubercle, and islands of Calleja complex (Cooper et al. 2003). They also function as projection neurons that connect different brain regions; one fairly well-characterized pathway runs from the septum to the hippocampus (Figure 2-6A). The cholinergic complex is composed of eight cholinergic nuclei from which cholinergic neurons originate, designated Ch1 to Ch8. The basal forebrain cholinergic nuclei include the medial septal nucleus (Ch1), the vertical nucleus of the diagonal band (Ch2), the horizontal limb of the diagonal band (Ch3), and the nucleus basalis of Meynert (Ch4); brain stem cholinergic nuclei include the pedunculopontine nucleus (Ch5), the laterodorsal tegmental nucleus (Ch6), the medial habenula (Ch7), and the parabigeminal nucleus (Ch8) (Nestler et al. 2015). These nuclei project cholinergic neurons to the entire nonstriatal telencephalon, pontomesencephalotegmental cholinergic complex, thalamus, and other diencephalic loci (see Figure 2-6A). Descending cholinergic projections from these nuclei also innervate pontine and medullary reticular formations, deep cerebellar and vestibular nuclei, and cranial nerve nuclei (Cooper et al. 2003; Nestler et al. 2015). Basal forebrain

cholinergic nuclei significantly degenerate in Alzheimer's disease, which can be mitigated to some extent with cholinergic agents that increase synaptic ACh, such as donepezil; conversely, anticholinergic agents such as benztropine and trihexyphenidyl, through brain stem cholinergic interneurons, modulate striatal dopaminergic neurons and partially counteract motor symptoms of Parkinson's disease ([Nestler et al. 2015](#)).

## Cholinergic Receptors

The two major distinct classes of cholinergic receptors are the *muscarinic* and *nicotinic* receptors. Five muscarinic receptors ( $M_1$  through  $M_5$ ) have been cloned ([Kandel 2013](#)). These receptors are G protein-coupled and act either by regulating ion channels (in particular,  $K^+$  or  $Ca^{2+}$ ) or through being linked to second-messenger systems. Generally speaking,  $M_1$ ,  $M_3$ , and  $M_5$  are coupled to phosphoinositol hydrolysis, whereas  $M_2$  and  $M_4$  are coupled to inhibition of adenylyl cyclase and regulation of  $K^+$  and  $Ca^{2+}$  channels ([Cooper et al. 2003](#)) (see [Figure 2-6B](#)).  $M_1$ ,  $M_3$ , and  $M_4$  receptors are located in the cerebral cortex and hippocampus, with the  $M_1$  and  $M_4$  receptors concentrated in the striatal motor and reward circuits; the  $M_5$  receptors are expressed widely at low levels; and the  $M_2$  presynaptic autoreceptors (which decrease ACh release into the synapse) are located in the basal forebrain ([Cannon et al. 2011](#); [Nestler et al. 2015](#)). Many older medications such as chlorpromazine (antipsychotic), benztropine (used for EPS), tricyclic antidepressants, and antihistamines also are antagonists of muscarinic receptors, and they cause common side effects such as dry mouth and constipation. One older muscarinic antagonist, scopolamine, commonly

known to help with seasickness, more recently was found in humans to have rapid antidepressant properties, and in rats, a single dose reversed chronic unpredictable stress anhedonia, potentially through a burst increase in glutamate, mTORC1 (mechanistic target of rapamycin complex 1), and synaptic spines in the medial PFC (Drevets et al. 2013; Navarria et al. 2015). Furthermore, one study showed that a TT homozygous polymorphism rs324650 in the fifth intron of the presynaptic M<sub>2</sub> autoreceptor gene (*CHRM2*) resulted in more severe illness, including increased risk for suicide, that was potentially related to the observed reduced total volume of distribution (V<sub>T</sub>) of M<sub>2</sub> receptors in the cingulate cortex of depressed bipolar patients, as measured by the high-affinity PET ligand M<sub>2</sub> receptor agonist [<sup>18</sup>F]FP-TZTP (Cannon et al. 2011). A conflicting postmortem observation detected no difference between bipolar patients and control subjects with the M<sub>2</sub>/M<sub>4</sub> receptor antagonist [<sup>3</sup>H]AFDX (Smith and Jakobsen 2009). This negative result with [<sup>3</sup>H]AFDX, as compared with the positive result with [<sup>18</sup>F]FP-TZTP, was potentially explained by a difference in the binding properties of the two radioligands (Cannon et al. 2011).

By contrast, the nicotinic receptors are ionotropic receptors, and at least 12 different functional receptors (based on different subunit composition) have been identified (Nestler et al. 2015). Biochemical and biophysical data indicate that the nicotinic receptors in the muscle are formed from five protein subunits around a central pore, with the stoichiometry of  $\alpha_2\beta\gamma\delta$  (Kandel 2013). The binding of ACh molecules on the  $\alpha$  subunit is necessary for channel activation. By contrast, neuronal nicotinic receptors contain only two types of subunits ( $\alpha$  and  $\beta$ ), with the  $\alpha$  occurring in

at least eight different forms and the  $\beta$  in three ([Cooper et al. 2003](#); [Nestler et al. 2015](#)). The most common nicotinic receptor subtypes are  $\alpha 4\beta 2$ -nACh and  $\alpha 7$ -nACh ([Horti et al. 2013](#)). Nicotinic receptors are the targets of considerable cross-talk, as a variety of kinases (including PKA, PKC, and tyrosine kinases) are able to regulate the sensitivity of this receptor. Several regulatory mechanisms exist. For example, the mammalian prototoxin lynx1 acts as an allosteric modulator of the nicotinic receptor ([Miwa et al. 2006](#)). Curare (a poisonous full nicotinic receptor antagonist used in poison-tipped arrows and so forth) and succinylcholine (a weak partial nicotinic receptor agonist and routine surgical muscle relaxant) are two examples of compounds affecting nicotinic receptors ([Nestler et al. 2015](#)).

From a clinical standpoint, a long-standing observation is that patients with schizophrenia have a rate of nicotine use disorder that is substantially higher than that in the general population, in both the prevalence (~90%) and the quantity of cigarettes smoked (chain smoking). This observation has led to numerous studies of medication targeting nicotinic receptors to try to alleviate symptoms of psychosis, including the use of nicotine replacement, but the results have been disappointing in terms of treating psychosis even though the nicotine replacement maintains cognitive functioning ([AhnAllen et al. 2015](#)). One report ([Freedman et al. 1997](#)) determined that in a cohort of patients with schizophrenia, abnormal P50 auditory evoked potentials were linked to a susceptibility locus for this disease on chromosome 15. Notably, this is where a nicotinic receptor subunit is found, providing indirect genetic and phenotypic support for the long-standing contention that the high rates of cigarette smoking in patients with schizophrenia may

represent some attempt by patients to self-medicate for their underlying nicotinic receptor defect. Varenicline, a partial agonist at the  $\alpha 4\beta 2$ -nACh receptor subtype developed for smoking cessation, helped patients with schizophrenia quit smoking but did not help them with their psychotic symptoms or cognitive deficits ([Smith et al. 2016](#)).

Although the PET radioactive ligand [ $^{11}\text{C}$ ]nicotine was one of the earliest human radioligands developed, it had problematic qualities as a PET ligand because of poor specificity and fast metabolism; the latest generation nicotinic ligand [ $^{18}\text{F}$ ]AZAN has some of the highest specific activity observed for the  $\alpha 4\beta 2$ -nACh receptor, and it was shown to be only partially blocked in the human brain by nicotine gum or secondhand smoke but completely blocked by the specific agonist varenicline ([Horti et al. 2013](#)). Despite the well-publicized long-term negative health consequences of smoking, tobacco products that contain nicotine remain one of the most widely used addictive legal substances in the world.

## Glutamatergic System

Glutamate and aspartate are the two major excitatory amino acids in the CNS and are present in high concentrations ([Nestler et al. 2015](#); [Squire 2013](#)). As the principal mediators of excitatory synaptic transmission in the mammalian brain, they participate in wide-ranging aspects of both normal and abnormal CNS function. Physiologically, glutamate appears to play a prominent role in synaptic plasticity, learning, and memory. However, glutamate can also be a neuronal excitotoxin under a variety of experimental conditions, triggering either rapid

or delayed neuronal death. Unlike the monoamines, which require transport of amino acids through the blood-brain barrier, glutamate and aspartate cannot adequately penetrate into the brain from the periphery and are produced locally by specialized brain machinery. The metabolic and synthetic enzymes responsible for the formation of these nonessential amino acids are located in glial cells and neurons ([Squire 2013](#)).

The major metabolic pathway in the production of glutamate is derived from glucose and the transamination of  $\alpha$ -ketoglutarate; however, a small proportion of glutamate is formed directly from glutamine. The latter is actually synthesized in glia, via an active process (requiring adenosine triphosphate [ATP]), and is then transported to neurons, where glutaminase is able to convert this precursor to glutamate ([Figure 2-7](#)). Following release, the concentration of glutamate in the extracellular space is highly regulated and controlled, primarily by a  $\text{Na}^+$ -dependent reuptake mechanism involving several transporter proteins.

**FIGURE 2-7.** The glutamatergic system.

*See **Plate 10** to view this figure in color.*

This figure depicts the various regulatory processes involved in glutamatergic neurotransmission. The biosynthetic pathway for glutamate involves synthesis from glucose and the transamination of  $\alpha$ -ketoglutarate; however, a small proportion of glutamate is formed more directly from glutamine by glutamine synthetase. The latter is actually synthesized in glia and, via an active process (requiring adenosine triphosphate [ATP]), is transported to neurons, where in the mitochondria glutaminase is able to convert this precursor to glutamate. Furthermore, in astrocytes glutamine can undergo oxidation to yield  $\alpha$ -ketoglutarate, which can also be transported to neurons and participate in glutamate synthesis. Glutamate is either metabolized or sequestered and stored in secretory vesicles by vesicle glutamate transporters (VGluTs). Glutamate can then be released by a calcium-dependent excitotoxic process. Once released from the presynaptic terminal, glutamate is able to bind to numerous excitatory amino acid (EAA) receptors, including both ionotropic (e.g., NMDA [*N*-methyl-D-aspartate]) and metabotropic (mGlu) receptors. Presynaptic regulation of glutamate release occurs through metabotropic glutamate receptors (mGlu2 and mGlu3), which subserve the function of autoreceptors; however, these receptors are also located on the postsynaptic element. Glutamate has its action terminated in the synapse by reuptake mechanisms utilizing distinct glutamate transporters that exist on not only presynaptic nerve terminals but also astrocytes; indeed, current data suggest that astrocytic glutamate uptake may be more important for clearing excess glutamate, raising the possibility that astrocytic loss (as has been documented in mood disorders) may contribute to deleterious glutamate signaling, but more so by astrocytes. It is now known that a number of important intracellular proteins are able to alter the function of glutamate receptors (see

diagram). Also, growth factors such as glial-derived neurotrophic factor (GDNF) and S100 $\beta$  secreted from glia have been demonstrated to exert a tremendous influence on glutamatergic neurons and synapse formation. Of note, serotonin<sub>1A</sub> (5-HT<sub>1A</sub>) receptors have been documented to be regulated by antidepressant agents; this receptor is also able to modulate the release of S100 $\beta$ . The major glutamate transporter proteins found in the CNS, all of which clear the released glutamate from synapses, include the Na<sup>+</sup>-dependent excitatory amino acid transporters (EAATs): the “faster turnover” EAATs—EAAT1 (or GLAST), EAAT2 (or GLT-1), and EAAT3 (or EAAC1); and the “slower turnover” EAATs—EAAT4 and EAAT5 ([Robinson and Jackson 2016](#)). The corresponding human gene names are *SLC1A3*, *2*, *1*, *6*, and *7*, respectively ([Robinson and Jackson 2016](#)). Additionally, these transporters are differentially expressed in specific cell types, with EAAT1 and EAAT2 being found primarily in glial cells, responsible for most of the glutamate reuptake, and EAAT3 being localized on both excitatory and inhibitory neurons and oligodendrocytes ([Robinson and Jackson 2016](#)). EAAT2 is the most predominantly expressed form in the forebrain; EAAT4 is mainly localized in Purkinje cells of the cerebellum but also found elsewhere; EAAT5 is on the presynaptic termini of bipolar neuronal cells of the retina ([Robinson and Jackson 2016](#); [Squire 2013](#)). Evidence indicates that phosphorylation of the transporters by protein kinases differentially regulates glutamate transporters and therefore glutamate reuptake ([Casado et al. 1993](#); [Conradt and Stoffel 1997](#); [Pisano et al. 1996](#)). Glutamate concentrations have been shown to rise to excitotoxic levels within minutes following traumatic or ischemic injury, and evidence indicates that the function of the glutamate transporters becomes impaired under these excitotoxic conditions ([Faden et al. 1989](#)). It is surprising that the glutamatergic system has only recently undergone extensive investigation with regard to its possible involvement in the pathophysiology of major mental illnesses, because it is the major excitatory neurotransmitter in the CNS and is known to play a role in

regulating the threshold for excitation of most other neurotransmitter systems. After decades of research exploring the classic dopamine dysfunction hypothesis as the pathophysiological basis for schizophrenia, the glutamate dysfunction hypothesis became an equally vigorous research effort on the basis of initial observations of the psychotogenic properties of phencyclidine (PCP) and ketamine. Both are NMDA receptor antagonists that acutely increase glutamate levels in the synapses, causing many of the core features of schizophrenia (psychosis, thought disorder, negative symptoms, and executive cognitive deficits) to emerge from otherwise healthy human subjects ([Moghaddam and Krystal 2012](#)). However, the enthusiasm for the use of ketamine-induced psychosis as a model for schizophrenia has dampened because of the lack of efficacy of haloperidol (a D<sub>2</sub> receptor antagonist) and group II metabotropic glutamate receptor (mGlu2/3) agonists in ameliorating ketamine-induced psychosis and the lack of genetic and postmortem data to support NMDA receptor dysfunction in schizophrenia ([Moghaddam and Krystal 2012](#)).

It is now clear that modification of the levels of synaptic AMPA-type glutamate receptors—in particular, by receptor subunit trafficking, insertion, and internalization—is a critically important mechanism for regulating various forms of synaptic plasticity and behavior. Studies have identified region-specific alterations in expression levels of AMPA and NMDA glutamate receptor subunits in patients with mood disorders ([Beneyto et al. 2007](#)). Supporting the suggestion that abnormalities in glutamate signaling may be involved in mood pathophysiology, AMPA receptors have been shown to regulate affectivelike behaviors in rodents. AMPA receptor antagonists have been found to attenuate

amphetamine- and cocaine-induced hyperactivity and psychostimulant-induced sensitization and hedonic behavior ([Goodwin et al. 2007](#)). Patients with treatment-resistant unipolar and bipolar depression given one intravenous dose of ketamine had strong relief of their depressive symptoms ([Berman et al. 2000](#); [Diazgranados et al. 2010](#); [Zarate et al. 2006a](#)). Ketamine antidepressant efficacy typically has been assumed to depend on direct glutamate NMDA receptor inhibition, which is how it works as an anesthetic ([Leung and Baillie 1986](#)). However, the results of human treatment trials indicate that alternative NMDA receptor antagonists lack the strong, rapid, or sustained antidepressant properties of ketamine ([Newport et al. 2015](#)). It has recently been shown that the metabolism of ketamine to one of its major metabolites, (2S,6S;2R,6R)-hydroxynorketamine, is essential for its antidepressant effects in mice ([Zanos et al. 2016](#)). These antidepressant actions are NMDA receptor inhibition independent, which requires activation of a different subtype of glutamate receptors, the AMPA receptors ([Zanos et al. 2016](#)).

## Glutamatergic Receptors

The many subtypes of glutamatergic receptors in the CNS can be classified into two major subtypes: ionotropic and metabotropic receptors (see [Figure 2-7](#)).

**Ionotropic glutamate receptors.** The ionotropic glutamate receptor ion channels are assemblies of homo- or hetero-oligomeric subunits integrated into the neuron's membrane. Every channel is assembled of (most likely) four subunits associated into a dimer of dimers, as has been observed in crystallographic studies ([Ayalon and Stern-Bach 2001](#); [Madden 2002](#); [Nestler et al. 2015](#)). Every

subunit consists of an extracellular amino-terminal and ligand binding domain, three transmembrane domains, a reentrant pore loop (located between the first and the second transmembrane domains), and an intracellular carboxyl-terminal domain ([Hollmann et al. 1994](#)). The subunits associate through interactions between their amino-terminal domains, forming a dimer that undergoes a second dimerization mediated by interactions between the ligand binding domains and/or between the transmembrane domains ([Ayalon and Stern-Bach 2001](#); [Madden 2002](#)). Three different subgroups of glutamatergic ion channels have been identified on the basis of their pharmacological ability to bind different synthetic ligands, each of which is composed of a different set of subunits. The three subgroups are the NMDA receptors, the AMPA receptors, and the kainate (KA) receptor. In the adult mammalian brain, NMDA and AMPA glutamatergic receptors are collocated in approximately 70% of the synapses ([Bekkers and Stevens 1989](#)). By contrast, at early stages of development, synapses are more likely to contain only NMDA receptors. Radioligand binding studies have shown that NMDA receptors and AMPA receptors are found at high densities in the cerebral cortex, hippocampus, striatum, septum, and amygdala.

*NMDA receptors.* The NMDA receptor is activated by glutamate and requires the presence of a co-agonist—namely, glycine or D-serine—to be activated, a process that likely varies in importance according to brain region ([Panatier et al. 2006](#)). However, the binding of both glutamate and glycine is still not sufficient for the NMDA receptor channel to open, because at resting membrane potential, the NMDA ion channel is blocked by  $Mg^{2+}$  ions.

Only when the membrane is depolarized (e.g., by the activation of AMPA or KA receptors on the same postsynaptic neuron) is the  $Mg^{2+}$  blockade relieved. Under these conditions, the NMDA receptor channel will open and permit the entry of both  $Na^+$  and  $Ca^{2+}$  (see [Figure 2-7](#)).

The NMDA receptor channel is composed of a combination of GluN1, GluN2A, GluN2B, GluN2C, GluN2D, GluN3A, and GluN3B subunits (see [Figure 2-7](#)). The binding site for glutamate has been localized to the GluN2 subunit, and the site for the co-agonist glycine has been localized to the GluN1 subunit, which is required for receptor function. Two molecules of glutamate and two of glycine are thought to be necessary to activate the ion channel. Within the ion channel, two other sites have been identified—the sigma ( $\sigma$ ) site and the PCP site. The hallucinogenic drugs PCP, ketamine, and the experimental drug dizocilpine (MK-801) all bind at the latter site and are considered noncompetitive receptor antagonists that inhibit NMDA receptor channel function.

In clinical psychiatric studies, ketamine has been shown to transiently induce psychotic symptoms in schizophrenic patients and to produce antidepressant effects in some depressed patients ([Krystal et al. 2002](#)). Building on these preclinical and preliminary clinical data, clinical trials have investigated the clinical effects of glutamatergic agents in patients with mood disorders. These and other data have led to the hypothesis that alterations in neural plasticity in critical limbic and reward circuits, mediated by AMPA and NMDA receptors, may represent a convergent mechanism for antidepressant action ([Zarate et al. 2006b](#)). Suicidal ideation also was rapidly improved with ketamine infusion ([Ballard et al. 2015](#)). This line of research holds considerable promise for developing new rapid-acting

treatments for refractory MDD and refractory bipolar depression. NMDA receptors in the amygdala also may be of critical importance in the process of transforming a fixed and consolidated fear memory to labile states ([Ben Mamou et al. 2006](#)). The hope of cognitive improvements through NMDA modulation was dashed by a meta-analysis of 17 studies of NMDA receptor agonists glycine, D-serine, and D-cycloserine and other glutamate-enhancing agents that did not show improvement in cognition in patients with schizophrenia ([Coyle et al. 2002](#); [Iwata et al. 2015](#)).

NMDA receptors play a critical role in regulating synaptic plasticity ([Malenka and Nicoll 1999](#); [Nestler et al. 2015](#)). The best-studied forms of synaptic plasticity in the CNS are *long-term potentiation* (LTP) and *long-term depression* (LTD) of excitatory synaptic transmission. The molecular mechanisms of LTP and LTD have been extensively characterized and have been proposed to represent cellular models of learning and memory ([Malenka and Nicoll 1999](#)). Induction of LTP and LTD in the CA1 region of the hippocampus and in many regions of the brain has now clearly been shown to be dependent on NMDA receptor activation. During NMDA receptor-dependent synaptic plasticity,  $\text{Ca}^{2+}$  influx through NMDA receptors can activate a wide variety of kinases and/or phosphatases that modulate synaptic strength. An important development was the finding that two of the primary molecules involved—CaMKII and the NMDA subtype of glutamate receptor—form a tight complex with each other at the synapse ([Lisman and McIntyre 2001](#)). Interestingly, this binding appears to enhance both the autophosphorylation of the kinase and the ability of the entire holoenzyme, which has 12 subunits, to become hyperphosphorylated ([Lisman and McIntyre 2001](#)). This hyperphosphorylated state has been

postulated to represent a “memory switch” that can lead to long-term strengthening of the synapse by multiple mechanisms. One important mechanism involves direct phosphorylation of the glutamate-activated AMPA receptors, which increases their conductance. Furthermore, CaMKII, once bound to the NMDA receptor, may organize additional anchoring sites for AMPA receptors at the synapse. Switching of synaptic NMDA receptor subunits, which bind CaMKII, for other NMDA receptor subunits having no affinity for this enzyme dramatically reduces LTP, highlighting glutamate and calcium signaling interactions critical for learning and memory ([Barria and Malinow 2005](#)).

Although the NMDA receptor clearly plays important roles in plasticity, abundant evidence has shown that excessive glutamatergic signaling is also involved in neuronal toxicity. With anoxia or hypoglycemia, the highly energy-dependent uptake mechanisms that keep glutamate compartmentalized in presynaptic terminals fail. Within minutes, glutamate is massively released into the synaptic space, resulting in activation of excitatory amino acid receptors. This leads to depolarization of target neurons via AMPA receptors and KA receptors and then to inappropriate and excessive activation of NMDA receptors ([Farber et al. 2002](#)). Considerable data suggest that the large excess of  $\text{Ca}^{2+}$  entering cells via the NMDA receptor channel may represent an important step in the rapid cell death that occurs via excitotoxicity ([Nestler et al. 2015](#)).

The hypothesis from the 1990s that NMDA receptor hypofunction is related to psychosis is supported by the observation of patients with autoimmune antibodies to the NMDA receptor (GluN1 subunit) who developed psychosis that reversed when the autoantibodies were removed by

plasmapheresis and immunosuppression ([Masdeu et al. 2016](#)). Anti-NMDA receptor encephalitis was first described in young women who had psychosis and ovarian teratomas in 2005, but it has since been found in both men and women who have no known malignancy, and even with treatment, patients have a high recurrence rate of 12% 2 years after treatment ([Pollak et al. 2014](#)). In one review of the literature, 1.46% of 1,441 psychotic patients who were tested had the immunoglobulin G antibodies, and an increase in extracellular glutamate was reported in rats injected with CSF from affected patients ([Manto et al. 2010](#); [Pollak et al. 2014](#)). Memantine, a noncompetitive NMDA receptor antagonist approved for the treatment of dementia, could be used as a possible treatment, especially in patients who proceed to develop catatonia or treatment-resistant schizophrenia ([Pollak et al. 2014](#)). Of note, patients with systemic lupus erythematosus also may develop antibodies to GluN2A and GluN2B subunits of the NMDA receptor treatment and have associated psychosis ([Pollak et al. 2014](#)). Encephalopathies have been found to be caused by an expanding list of autoimmune markers, including AMPA receptors, glycine receptors, and GABA<sub>A</sub> and GABA<sub>B</sub> receptors, all to be discussed later in this chapter ([McKeon 2016](#)).

In postmortem studies of patients with MDD who committed suicide, the PFC region had decreased levels of GluN2A and GluN2B subunits and the postsynaptic density protein-95 but no change in the level of the mandatory GluN1 subunits as compared with control subjects ([Feyissa et al. 2009](#)). Acamprosate (*N*-acetylhomotaurine) is an NMDA receptor antagonist approved for the treatment of alcohol use disorder, based on its success in decreasing cravings in clinical trials, but because it is short acting,

patients must take this medication three times a day ([Haass-Koffler et al. 2014](#)).

*AMPA receptors.* The AMPA receptor is stimulated by the presence of glutamate and characteristically produces a fast excitatory synaptic signal that is responsible for the initial reaction to glutamate in the synapse. In fact, as discussed earlier, researchers generally believe that the activation of the AMPA receptor results in neuronal depolarization sufficient to liberate the  $Mg^{2+}$  cation from the NMDA receptor, thereby permitting its activation. The AMPA receptor channel is composed of the combination of the GluA1, GluA2, GluA3, and GluA4 subunits and requires two molecules of glutamate to be activated (see [Figure 2-7](#)). AMPA receptors have a lower affinity for glutamate than does the NMDA receptor, thereby allowing for more rapid dissociation of glutamate and, therefore, a rapid deactivation of the AMPA receptor ([Henley and Wilkinson 2016](#)).

Studies have indicated that AMPA receptor subunits are direct substrates of protein kinases and phosphatases. Phosphorylation of the receptor subunits regulates not only the intrinsic channel properties of the receptor but also the interaction of the receptor with associated proteins that modulate the membrane trafficking and synaptic targeting of the receptors ([Malinow and Malenka 2002](#)). Additionally, protein phosphorylation of other synaptic proteins has been proposed to indirectly modulate AMPA receptor function by affecting the macromolecular complexes that are important for the presence of AMPA receptors at the synaptic plasma membrane ([Malinow and Malenka 2002](#); [Nestler et al. 2015](#)). Studies have been elucidating the cellular mechanisms by which AMPA receptor subunit insertion and

trafficking occur and have identified two major mechanisms ([Malinow and Malenka 2002](#); [Nestler et al. 2015](#)). The first mechanism is used for GluA1-containing AMPA receptor insertion and is regulated by activity. The second mechanism is governed by constitutive receptor recycling, mainly through GluA2/3 heteromers in response to activity-dependent signals. Data suggest that AMPA receptor subunit trafficking may play an important role in neuropsychiatric disorders and addictions. Thus, Nestler and associates have shown that the ability of drugs of abuse to elevate levels of the GluA1 subunit of AMPA glutamate receptors in the VTA of the midbrain is crucial for the development of sensitization ([Carlezon and Nestler 2002](#)). They have found that even transient increases in GluA1 levels within VTA neurons can trigger complex cascades of other molecular adaptations in these neurons and, within larger neural circuits, can cause enduring changes in the responses of the brain to drugs of abuse. Chronic lithium and valproate have been shown to reduce GluA1 expression in hippocampal synaptosomes, which may play a role in the delayed therapeutic effects of these agents ([Du et al. 2003](#); [Szabo et al. 2009](#)).

Differential trafficking of AMPA receptor subunits as the sole, classic mechanism for regulation and induction of LTP was recently challenged when knockout mouse models demonstrated that LTP occurred even with no AMPA receptors but only KA receptors ([Henley and Wilkinson 2016](#)). One possible hypothesis that results from this observation would be that the subunits of the AMPA receptors do not dictate plasticity, but perhaps the numbers of “slot proteins” or “placeholder proteins” influence the development of LTP, and LTP is AMPA receptor subunit independent ([Henley and Wilkinson 2016](#)).

Investigators have sought to test the hypothesis that these “antidepressant anticonvulsants,” like traditional antidepressants, would enhance surface AMPA receptors ([Du et al. 2007](#)). It was found that lamotrigine and riluzole significantly enhanced the surface expression of GluA1 and GluA2 in a time- and dose-dependent manner in cultured hippocampal neurons. By contrast, the antimanic anticonvulsant valproate significantly reduced surface expression of GluA1 and GluA2. Concomitant with the GluA1 and GluA2 changes, the peak value of depolarized membrane potential evoked by AMPA was significantly higher in lamotrigine- and riluzole-treated neurons, supporting the surface receptor changes. In addition, lamotrigine and riluzole, as well as the traditional antidepressant imipramine, increased GluA1 phosphorylation at GluA1 (S845) in the hippocampus after chronic in vivo treatment.

Clinical studies have reported a consistent and rapid antidepressant effect of ketamine. Studies were therefore undertaken to test the hypothesis that ketamine brings about its rapid antidepressant effect via an AMPA receptor-dependent mechanism ([Maeng et al. 2008](#)). The AMPA receptor antagonist NBQX was without behavioral effects alone but blocked the antidepressant-like effects of ketamine. AMPA receptor antagonists also blocked the ketamine-induced changes in hippocampal GluA1 AMPA receptor phosphorylation ([Maeng et al. 2008](#)). It was also recently observed that these actions are observed with a metabolite of ketamine, (2R,6R)-hydroxynorketamine, which also causes strong and rapid potentiation of AMPA receptors ([Zanos et al. 2016](#)). Together, these results suggest that increased AMPA receptor activity in critical

mood-relevant circuits may play an important role in antidepressant action.

*Kainate receptors.* The KA receptor has pre- and postsynaptic roles, sharing some properties with AMPA receptors. It is composed of the combination of the GluK1, GluK2, and GluK3 low-affinity subunits co-assembling with the GluK4 or GluK5 high-affinity subunits (formerly called the GluR5, GluR6, GluR7, KA1, and KA2 subunits, respectively) to form a dimer of dimers (tetrameric complex) (see [Figure 2-7](#)) ([Møllerud et al. 2017](#)). The crystal structures suggest that the pore remains closed even with glutamate bound to it, indicating that an additional mechanism is required to induce conformational change to open the pore ([Møllerud et al. 2017](#)). The precise role of KA receptors in the mature CNS is unknown, although the activity of the receptors clearly plays a role in synaptic function in many brain areas. Increasing data suggest the involvement of aberrant synaptic plasticity in the pathophysiology of bipolar disorder. KA receptors contribute to synaptic plasticity in different brain regions involved in mood regulation, including PFC, hippocampus, and amygdala. GluK2 (formerly called GluR6; the gene name continues to be *GRIK2*) is a subtype of KA receptor whose chromosomal loci of 6q16.3-q21 was identified as potentially harboring genetic polymorphism(s) contributing to the increased risk of mood disorders. The role of GluK2 in modulation of animal behaviors correlated with mood symptoms was investigated with GluK2 knockout mice and wild-type mice ([Shaltiel et al. 2007](#)). GluK2 knockout mice appeared to attain normal growth and lacked neurological abnormalities. The GluK2 knockout mice showed increased basal- or amphetamine-induced activity, were extremely

aggressive, took more risks, and consumed more saccharin (a measure of hedonic drive). Notably, most of these aberrant behaviors responded to chronic lithium administration. These results suggest that abnormalities in KA receptor throughput generated by GluK2 gene disruption may lead to the concurrent appearance of a constellation of behaviors related to manic symptoms, including persistent hyperactivity, escalated irritability and aggression, risk taking, and hyperhedonia.

KA receptors play an important role in the hippocampus with place cell activity patterns and working memory ([Sihra and Rodríguez-Moreno 2013](#)). KA receptors modulate glutamate release between the mossy fibers of the granular cells of the dentate gyrus and the principal cells of the CA3 region, and there is high expression of KA receptors at those mossy fiber-CA3 synapses ([Sihra and Rodríguez-Moreno 2013](#)). KA receptors both prevent excessive glutamate release and facilitate increased glutamate release when the levels of glutamate are low in those same synapses ([Sihra and Rodríguez-Moreno 2013](#)). Recovery of the synapses with KA receptors is long and slow compared with the fast NMDA receptors, which may assist with memory formation ([Sihra and Rodríguez-Moreno 2013](#)). The CA3 may be more prone to develop seizures as a result of the KA receptors facilitating glutamate release ([Sihra and Rodríguez-Moreno 2013](#)).

**Metabotropic glutamate receptors.** The metabotropic glutamate (mGlu) receptors are GPCRs. The eight types of receptors that have been cloned can be organized into three different subgroups (groups I, II, and III) based largely on the signaling transduction pathways that they activate (see [Figure 2-7](#)). These receptors have a

large extracellular N-terminal consisting of two lobes forming a “venus flytrap” binding pocket involved in glutamate recognition and a cysteine-rich extracellular domain that connects with seven transmembrane domains separated by short intra- and extracellular loops (see [Figure 2-7](#)). The intracellular loop plays an important role in the coupling with and selectivity of the G protein. The cytoplasmic carboxyl-terminal domain is variable in length and is involved with G protein activation and coupling efficacy ([Bruno et al. 2001](#); [Conn and Pin 1997](#); [Nestler et al. 2015](#)).

The mGlu receptor group I includes the mGlu1 (a, b, c, d) and mGlu5 (a, b) receptors (see [Figure 2-7](#)). They preferentially interact with the  $G_{\alpha q/11}$  subunit of G proteins, leading to activation of the  $IP_3$ /calcium and DAG/PKC cascades. The receptors are located on both pre- and postsynaptic neurons. Group II metabotropic receptors include mGlu2 and mGlu3, which have been best characterized as inhibiting adenylyl cyclase, but, like many receptors coupled to  $G_i/G_o$ , may also regulate ion channels. Group III receptors, which include mGlu4 (a, b), mGlu6, mGlu7 (a, b), and mGlu8 (a, b), are reported to produce inhibition of adenylyl cyclase as well but also to interact with the phosphodiesterase enzyme regulating guanosine monophosphate levels ([Cooper et al. 2003](#); [Squire 2013](#)). The group II and III receptors are located in the presynaptic membrane and, because of their coupling with  $G_i/G_o$  proteins, appear to negatively modulate glutamate and GABA neurotransmission output when activated (i.e., they serve as inhibitory auto- and heteroreceptors). Preclinical studies suggest that mGlu group II and III receptors are “extrasynaptic” in their localization; that is,

they are located some distance from the synaptic cleft and are thus activated only under conditions of excessive (pathological?) glutamate release, when glutamate is sufficient to diffuse out of the synapse to these receptors ([Schoepp 2001](#)). In preclinical studies, mGlu2/3 receptor agonists have been found to exert anxiolytic, antipsychotic, and neuroprotective properties ([Schoepp 2001](#)). However, subsequent clinical trials in humans have not sustained the promise of the preclinical studies ([Moghaddam and Krystal 2012](#)). mGlu receptors of all three groups appear to work as inhibitory autoreceptors, decreasing release of glutamate from the synapse, modulating glutamate release ([Nestler et al. 2015](#)).

Postmortem studies of the brains of patients with MDD who committed suicide reported several changes in expression of mGlu receptors. Patients with MDD have higher levels of RNA gene expression as measured by quantitative polymerase chain reaction for NMDA receptor subunits GluN2B and GluN2C, as well as for metabotropic receptors mGlu4 and mGlu5 in the neurons of the locus coeruleus, which together serve to stimulate noradrenergic neurons located there ([Chandley et al. 2014](#)). According to one study, Brodmann area 10 of the PFC of depressed and/or suicidal individuals had a 67% increase in (mostly presynaptic) mGlu2 and mGlu3 protein levels compared with healthy control subjects ([Feyissa et al. 2010](#)). Another study showed decreased mGlu5 protein expression in postmortem brain samples corresponding to decreased regional binding of a PET ligand to mGlu5 receptors in living depressed patients ([Deschwanden et al. 2011](#)). These observations suggest that there may be a relative glutamate “deficiency” in the synapse, leading to increased expression of glutamate receptors in depressed patients.

# Glycine

---

Glycine is a nonessential amino acid that also functions as a neurotransmitter in the CNS, serving as a co-agonist for NMDA receptor activation. Glycine may be produced in the CNS by two distinct pathways. First, glycine is produced from serine by the enzyme serine-*trans*-hydroxymethylase in a reversible, folate-dependent reaction ([Cooper et al. 2003](#); [Nestler et al. 2015](#); [Squire 2013](#)). Second, a smaller proportion of glycine also may be produced from glyoxylate by the enzyme D-glycerate dehydrogenase. Glycine is found in higher concentrations in the spinal cord than in the rest of the CNS, and it acts as an inhibitory neurotransmitter predominantly in the brain stem and spinal cord ([Nestler et al. 2015](#)). As discussed earlier, a very important role that glycine also plays is to augment the NMDA-mediated frequency of NMDA receptor channel opening. This effect is strychnine-insensitive and pharmacologically suggests that the actions of glycine on NMDA receptor function are different from its effect on the spinal cord, where glycine's inhibitory effect is blocked by strychnine ([Cooper et al. 2003](#)). The allosteric modulation of NMDA receptors via a glycine site is further underscored by receptor binding experiments yielding an anatomical distribution similar to that of NMDA receptors. Functionally, it has been postulated that glycine is able to augment the NMDA-mediated responses by speeding up the recovery process of the NMDA receptor ([Cooper et al. 2003](#)).

Glycine receptors, similar to GABA<sub>A</sub> receptors, contain a chloride channel, and are composed of a combination of three  $\alpha$  subunits containing the glycine binding site and two  $\beta$  subunits, which associate with gephyrin, a cytoplasmic

protein ([Nestler et al. 2015](#)). Glycine receptors are bound by the compounds strychnine, a selective glycine receptor antagonist, and picrotoxin, a noncompetitive inhibitor, which block the chloride channel pore and cause seizures ([Nestler et al. 2015](#)). Synaptic glycine is removed mostly through the glycine transporter GlyT1. Ligands to GlyT1 are being explored as potential candidates for the treatment of schizophrenia, and a specific PET ligand, [ $^{18}\text{F}$ ]MK6577, recently has been developed ([Xia et al. 2015](#)). The endogenous ligands for the glycine receptor are actually D-serine and D-cycloserine ([Labrie and Roder 2010](#)). Glycine receptor agonism (D-serine) or GlyT antagonism (sarcosine) effectively increases glycine in the synapse, causing an increase in NMDA GluN1 receptor activation, which may ameliorate symptoms of schizophrenia, and clinical trials have suggested that these compounds may be helpful as augmentation agents together with other antipsychotics ([Labrie and Roder 2010](#)).

## GABAergic System

---

GABA—the major inhibitory neurotransmitter system in the CNS—is one of the most abundant neurotransmitters, and GABA-containing neurons are located in virtually every area of the brain. Unlike the monoamines, GABA occurs in the brain in high concentrations on the order of micromoles per milligrams (about 1,000-fold higher than concentrations of monoamines) ([Cooper et al. 2003](#); [Nestler et al. 2015](#); [Squire 2013](#)). GABA is produced when glucose is converted to  $\alpha$ -ketoglutarate, which is then transaminated to

glutamate by GABA  $\alpha$ -oxoglutarate transaminase (GABA-T). Glutamic acid is decarboxylated by glutamic acid decarboxylase, which leads to the formation of GABA (Figure 2-8). Indeed, the neurotransmitter and the rate-limiting enzyme are localized together in the brain and at approximately the same concentration. Catabolism of GABA occurs via GABA-T, which is also important in the synthesis of this transmitter.

---

## **FIGURE 2-8.** The GABAergic system.

*See [Plate 11](#) to view this figure in color.*

This figure depicts the various regulatory processes involved in GABAergic neurotransmission. The amino acid (and neurotransmitter) glutamate serves as the precursor for the biosynthesis of  $\gamma$ -aminobutyric acid (GABA). The rate-limiting enzyme for the process is glutamic acid decarboxylase (GAD), which utilizes pyridoxal phosphate as an important cofactor. Furthermore, agents such as L-glutamine- $\gamma$ -hydrazide and allylglycine inhibit this enzyme and, thus, the production of GABA. Once released from the presynaptic terminal, GABA can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of GABA neuron firing activity and release occurs through somatodendritic (not shown) and nerve-terminal GABA<sub>B</sub> receptors, respectively. Baclofen is a GABA<sub>B</sub> receptor agonist. The binding of GABA to ionotropic GABA<sub>A</sub> receptors and metabotropic GABA<sub>B</sub> receptors mediates the effects of this receptor. The GABA<sub>B</sub> receptors are thought to mediate their actions by being coupled to  $\text{Ca}^{2+}$  or  $\text{K}^{+}$  channels via second-messenger systems. Many agents are able to modulate GABA<sub>A</sub> receptor function. Benzodiazepines, such as diazepam, increase  $\text{Cl}^{-}$  permeability, and there are numerous available antagonists directed against this site. There is also a distinctive barbiturate binding site on GABA<sub>A</sub> receptors, and many psychotropic agents are capable of influencing the function of this receptor (see blown-up diagram). GABA is taken back into presynaptic nerve endings by a high-affinity GABA uptake transporter (GABAT) similar to that of the monoamines. Once inside the neuron, GABA can be broken down by GABA transaminase (GABA-T), which is localized in the mitochondria; GABA that is not degraded is sequestered and stored in secretory vesicles by vesicular GABA transporters (VGATs), which differ from vesicular monoamine transporters (VMATs) in their bioenergetic dependence.

The metabolic pathway that produces GABA, mostly from glucose, is referred to as the *GABA shunt*. The conversion of  $\alpha$ -ketoglutarate into glutamate by the action of GABA-T and GAD catalyzes the decarboxylation of glutamic acid to produce GABA. GABA can undergo numerous transformations, of which the simplest is the reduction of succinic semialdehyde (SS) to  $\gamma$ -hydroxybutyrate (GHB). On the other hand, when SS is oxidized by succinic semialdehyde dehydrogenase (SSADH), the production of succinic acid (SA) occurs. GHB has received attention because it regulates narcoleptic episodes and may produce amnestic effects. The mood stabilizer and antiepileptic drug valproic acid is reported to inhibit SSADH and GABA-T. AC=adenylyl cyclase; TBPS=*t*-butylbicyclophosphorothionate.

The contrasting functions of GABA-T, an enzyme able to synthesize both glutamate and the opposing GABA neurotransmitters as well as to catabolize GABA, become apparent when GABA-T is placed in the context of its role in the metabolic process. GABA-T converts GABA to succinic acid, and subsequent removal of the amino group yields  $\alpha$ -ketoglutarate. Thus,  $\alpha$ -ketoglutarate is able to be used by GABA-T in GABA biosynthesis as mentioned earlier ([Cooper et al. 2003](#)). This process, called the *GABA shunt*, maintains a steady GABA supply in the brain. As with the monoamines, the major mechanism by which the effects of GABA are terminated in the synaptic cleft is by reuptake through GABA transporters. The GABA transporters have a high

affinity for GABA and mediate their reuptake via a  $\text{Na}^+$  and  $\text{Cl}^-$  gradient ([Squire 2013](#)).

Studies have measured the density and size of calbindin-immunoreactive neurons (presumed to be GABAergic) in layers II and III of the dorsolateral PFC, reporting a 43% reduction in the density of these neurons in patients with MDD compared with control subjects ([Rajkowska 2002](#)). Of particular note, in the rostral orbitofrontal cortex, there was a trend toward a negative correlation between the duration of depression and the size of neuronal cell bodies, suggesting changes associated with disease progression. Valproate also has been shown to have neurogenic effects in at least one study. In cultured embryonic rat cortical cells and striatal primordial stem cells, valproate markedly increased the number and percentage of primarily GABAergic neurons and increased neurite outgrowth ([Laeng et al. 2004](#)).

Low levels of GABA were observed in patients with MDD, particularly in the occipital and prefrontal cortex of living patients as well as in postmortem brain samples of people with MDD, some of whom committed suicide ([Maciag et al. 2010](#)). Specifically, the calbindin immunoreactive GABAergic neurons of the occipital lobe were decreased by 28% in depressed individuals as compared with control subjects, consistent with previous observations of differences in visual evoked potentials between depressed and healthy populations ([Maciag et al. 2010](#)). In addition, a PET study that used [ $^{11}\text{C}$ ]flumazenil, a ligand for the benzodiazepine site of the  $\text{GABA}_A$  receptor, reported decreased GABA transmission in the medial temporal lobe of living antipsychotic-naïve patients with schizophrenia, consistent with postmortem studies showing lower GABA in the cortex ([Frankle et al. 2015](#); [Lewis et al. 2005](#)).

# GABA Receptors

The two major types of well-characterized GABA receptors are GABA<sub>A</sub> and GABA<sub>B</sub>, and most neurons in the CNS possess at least one of these types. The GABA<sub>A</sub> receptor is the more prevalent of the two in the mammalian CNS, and as a result has been extensively studied and characterized. GABA<sub>A</sub> contains an integral transmembrane chloride channel, which is opened on receptor activation, generally resulting in hyperpolarization of the neuron (i.e., suppressing excitability) ([Nestler et al. 2015](#)). The GABA receptor is a heteropentameric glycoprotein of approximately 275 kDa composed of a combination of multiple polypeptide subunits. GABA<sub>A</sub> shows enormous heterogeneity, being composed of a combination of five classes of polypeptide subunits ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\epsilon$ ), of which there are at least 18 total subtypes ([Nestler et al. 2015](#)). The various receptors have variation in functional pharmacology, hinting at the multiple finely tuned roles that inhibitory neurotransmission plays in brain function.

It is now well established that benzodiazepines function by binding to a potentiator site on the GABA<sub>A</sub> receptor, increasing the amplitude and duration of inhibitory postsynaptic currents in response to GABA binding. Coexpression of additional  $\gamma$  subunits is believed to be necessary for the potentiation of GABA-mediated responses by benzodiazepines. In addition to benzodiazepines, barbiturates and ethanol are believed to exert many of their effects by potentiating the opening of the GABA<sub>A</sub> receptor chloride channel (see [Figure 2-8](#)) ([Nestler et al. 2015](#)). As noted earlier, GABA<sub>A</sub> receptors have a widespread distribution in the brain, and most of these receptors in the

brain are targets of the currently available benzodiazepines. For this reason, there has been considerable interest in determining whether the desirable and undesirable effects of benzodiazepines can be differentiated on the basis of the presence of a different subunit composition. Much of the work has used gene knockout technology; thus, mutation of the benzodiazepine binding site of the  $\alpha_1$  subunit in mice blocks the sedative, anticonvulsive, and amnesic, but not the anxiolytic, effects of diazepam ([Gould et al. 2003](#); [Möhler et al. 2002](#)). In contrast, the  $\alpha_2$  subunit (expressed highly in the cortex and hippocampus) is necessary for diazepam anxiolysis and myorelaxation. Thus, an  $\alpha_2$ -selective ligand would provide effective acute treatment of anxiety disorders without the unfavorable side-effect profile of benzodiazepines. A compound with this preferential affinity for  $\alpha_2$  has been reported to exert fewer sedative and depressant effects than diazepam in rat behavioral studies ([Gould et al. 2003](#); [Möhler et al. 2002](#)).

The phosphorylation of GABA<sub>A</sub> receptors is another mechanism by which this receptor complex can be regulated in function and expression. In this context, it is noteworthy that studies have shown that knockout mice deficient in PKC  $\epsilon$  isoforms show reduced anxiety and alcohol consumption and an enhanced response to effects of benzodiazepines (discussed in [Gould et al. 2003](#)). Furthermore,  $\alpha/\delta$  subunit assemblies are a novel neuronal GABA<sub>A</sub> receptor subunit partnership present in hippocampal interneurons, which functions to mediate tonic inhibitory currents. Notably, this assembly results in a complex that is highly sensitive to low concentrations of ethanol ([Glykys et al. 2007](#)).

The GABA<sub>B</sub> receptors are coupled to G<sub>i</sub> and G<sub>o</sub> and thereby regulate adenylyl cyclase activity (generally inhibit), K<sup>+</sup> channels (open), and Ca<sup>2+</sup> channels (close). GABA<sub>B</sub> receptors can function as an autoreceptor but are also found abundantly postsynaptically on non-GABAergic neurons. Of interest, mounting evidence indicates that receptor dimerization may be required for the activation of GABA<sub>B</sub> and possibly other GPCRs; although receptor dimerization has long been known to occur for growth factor and JAK (Janus tyrosine kinase)/STAT (signal transducers and activators of transcription) receptors, this was not expected for GPCRs. However, studies have reported that coexpression of two GABA<sub>B</sub> receptor subunits—subunit 1 (GABA<sub>B1</sub>) and subunit 2 (GABA<sub>B2</sub>)—is necessary for the formation of a functional GABA<sub>B</sub> receptor ([Bouvier 2001](#)). Data suggest that GABA<sub>B2</sub> receptor subunits may be necessary for proper protein folding of GABA<sub>B1</sub> receptor subunits (acting as a molecular chaperone) in the endoplasmic reticulum, but this remains to be definitively established. Support for the physiological relevance of this dimerization comes from studies showing that the GABA<sub>B1</sub> and GABA<sub>B2</sub> receptor subunits can be co-immunoprecipitated in rat cortical membrane preparations ([Kaupmann et al. 1997](#)); thus, the dimerization is not simply an in vitro phenomenon.

Relatively new GABAergic agents include zolpidem, a short-acting, positive allosteric modulator of the benzodiazepine site of the GABA<sub>A</sub> receptor that is used for initial insomnia; gaboxadol, a  $\delta$ -subunit-selective extrasynaptic GABA<sub>A</sub> receptor agonist; and tiagabine, a GABA reuptake inhibitor (blocks the GABA membrane

transporter GAT1) used as an anticonvulsant ([Nutt et al. 2015](#)). Alcohol and benzodiazepines both notably bind GABA<sub>A</sub> receptors and are cross-reactive with each other, to the point that benzodiazepines are used routinely to detoxify patients from alcohol intoxication while simultaneously avoiding precipitating seizures. Baclofen is a GABA<sub>B</sub> receptor agonist used to treat muscle spasms. Methaqualone, a sedative GABA<sub>A</sub> receptor agonist widely prescribed in the 1960s as a safe alternative to barbiturates, was taken off the market when it was found to be highly addictive and was abused in combination with alcohol ([Hammer et al. 2015](#)). Propofol, an anesthetic agent that has been in the news for abuse potential and accidental overdoses among famous celebrities, also binds the GABA<sub>A</sub> receptor in a manner similar to barbiturates and methaqualone, which all are highly addictive and keep the chloride channel open longer ([Hammer et al. 2015](#)).

## Purinergic Neurotransmission: Focus on Adenosine

---

It has been known for quite some time that ATP is capable of exerting profound effects on the nervous system ([Drury and Szent-Györgyi 1929](#)). However, adenosine and adenosine nucleotides have become more widely accepted as neuroactive substances in the CNS ([Cooper et al. 2003](#)). Adenosine is released from neurons and glia, but many of the neurotransmitter criteria outlined in the beginning of this chapter are not met. Nonetheless, adenosine is able to activate many cellular functions that can produce changes

in neuronal and behavioral states. For instance, adenosine stimulates cAMP in vitro in brain slices, and caffeine (which in addition to being a phosphodiesterase inhibitor is a well-known adenosine receptor antagonist) is able to block this response.

In the P1 (for purine) adenosine receptor class, four adenosine receptors have been cloned ( $A_1$ ,  $A_{2A}$ ,  $A_{2B}$ , and  $A_3$ ), each of which has a unique tissue distribution, ligand binding affinity (nanomolar range), and signal transduction mechanisms ([Cooper et al. 2003](#)). Data suggest that the high-affinity adenosine receptors ( $A_1$  and  $A_{2A}$ ) may be activated under normal physiological conditions, whereas in pathological states such as hypoxia and inflammation (in which high adenosine concentrations [micromolar range] are present), low-affinity  $A_{2B}$  and  $A_3$  receptors are also activated.  $A_{2B}$  receptors are expressed in low levels in the brain but are ubiquitous in the rest of the body, whereas  $A_{2A}$  receptors are found in high concentrations in areas of the brain that receive dopaminergic projections (i.e., striatum, nucleus accumbens, and olfactory tubercle) ([Nestler et al. 2015](#)). Given this receptor's distribution, and the inverse relation between dopamine and adenosine, it has been postulated that  $A_{2A}$  antagonists may have some utility in the treatment of Parkinson's disease ([Nestler et al. 2015](#)). The mood stabilizer and antiepileptic drug carbamazepine, which primarily works through blocking voltage-gated sodium channels, also acts as an antagonist of the  $A_1$  subtype, which is epileptogenic in some vulnerable populations, such as children ([Booker et al. 2015](#); [Gould et al. 2002](#)).

Adenosine is also able to alter the function (both pre- and postsynaptically) of numerous neurotransmitters and their

receptors, including NMDA, mGlu receptors, ionotropic nicotinic receptors, norepinephrine, serotonin, dopamine, GABA, and various peptidergic receptors. Adenosine is widely regarded as a major component that regulates homeostasis of blood flow and metabolic demands in peripheral tissue physiology. Evidence suggests that adenosine is implicated as a fatigue factor to decrease cholinergic activity-arousal via presynaptic inhibition of glutamate release ([Brambilla et al. 2005](#)). In addition, the ionotropic ligand-gated P2X trimeric receptor class (containing seven subtypes: P2X<sub>1</sub> through P2X<sub>7</sub>) and the metabotropic GPCR P2Y receptor class (containing subtypes P2Y<sub>1</sub>, P2Y<sub>2</sub>, P2Y<sub>4</sub>, P2Y<sub>6</sub>, P2Y<sub>11</sub>, P2Y<sub>12</sub>, P2Y<sub>13</sub>, and P2Y<sub>14</sub>) are purine receptors that can be activated by ATP ([Nestler et al. 2015](#); [Ortiz et al. 2015](#)). It has been found that ATP is released from astrocytes (through an unknown mechanism) and that the release is accompanied by glutamate release (Ca<sup>2+</sup>-dependent) ([Innocenti et al. 2000](#)). However, more data suggest adenosine (which is derived from ATP) may serve as the true ligand for these purinergic receptors ([Fields and Stevens-Graham 2002](#)). The ATP/adenosine is then able to activate purine receptors (P2Y receptors) on neighboring astrocytes, and this stimulates Ca<sup>2+</sup> influx and subsequent release of glutamate and ATP to then affect other astrocytes and neurons. This may be a critical component in the communication process between glial cells, as well as representing a signaling molecule from glia to neurons ([Fields and Stevens-Graham 2002](#)).

Caffeine in coffee, theophylline in tea, and theobromine in cocoa are all methylxanthine compounds that at moderate doses cause increased alertness through antagonizing the

A<sub>1</sub>—and, to a lesser extent, the A<sub>2A</sub>—receptors, but in susceptible people at higher doses, they cause anxiety and even panic attacks ([Nestler et al. 2015](#)). Adenosine A<sub>1</sub> agonists may have neuroprotective effects in stroke both by inhibiting glutamate release (excitotoxicity) presynaptically and by inhibiting postsynaptic membrane depolarization and calcium influx (exacerbating excitotoxicity) ([Nestler et al. 2015](#)). Because the striatum has high levels of A<sub>2A</sub> receptors, A<sub>2A</sub> receptor antagonists are being explored for the treatment of Parkinson's disease-related L-dopa-induced hyperkinesia due to the inverse relation between adenosine and dopamine in the striatum. P2X<sub>3</sub> and P2X<sub>2/3</sub> receptors are being explored for pain modulation ([Nestler et al. 2015](#)). The literature is conflicted as to whether adenosine analogues cause depression or treat depression, but low brain purine levels have been reported in depressed female patients ([Krügel 2016](#)). Evidence has also increased in the literature that schizophrenia may be a hypoadenosinergic state, such as reduced A<sub>2A</sub> receptors in postmortem brain samples ([Krügel 2016](#)). Numerous adenosine PET ligands to adenosine receptors have been developed ([Mishina and Ishiwata 2014](#)).

## Peptidergic Neurotransmission

---

Neuropeptides have garnered increasing attention as critical modulators of CNS function. In general, peptide transmitters are released from neurons when they are stimulated at higher frequencies than those required to facilitate release of traditional neurotransmitters but can also be co-localized and co-released together with other

neurotransmitters ([Cooper et al. 2003](#); [Nestler et al. 2015](#)). Modulation of the firing rate pattern of neurons and subsequent release of neurotransmitters and peptides in a circumscribed fashion are likely important in the basal functioning of the brain, as well as response to specific stimuli. Interestingly, cannabinoids, an example of a neuropeptide neurotransmitter, do not alter firing rates of hippocampal neurons but change temporal coordination, an effect that correlates with memory deficits in individuals ([Soltesz and Staley 2006](#)). Localization of brain stem cannabinoid receptors (CB<sub>1</sub> and CB<sub>2</sub>) provided clues to how cannabinoids regulate brain function ([Van Sickle et al. 2005](#)). Virtually every known mammalian bioactive peptide is synthesized first as a precursor protein in which product peptides are flanked by cleavage sites. Neuropeptides are generally found in large dense-core vesicles, whereas other neurotransmitters, such as the monoamines, are packaged in small synaptic vesicles (approximately 50 nm) and are usually half the size of their peptidergic counterparts ([Kandel 2013](#); [Squire 2013](#)).

Space limitations preclude an extensive discussion of the diverse array of neuropeptides known to exist in the mammalian brain. [Table 2-2](#) highlights some of the major neuropeptides that may be of particular psychiatric relevance. In the remainder of this section, we highlight the basic aspects of peptidergic transmission vis-à-vis an overview of opiodergic neurotransmission. We briefly discuss selected neuropeptides here; a general review of neuropeptides as potential drug targets can be found elsewhere ([Hoyer and Bartfai 2012](#)).

## Corticotropin-Releasing Factor

Hyperactivity of the hypothalamic-pituitary-adrenal (HPA) axis may relate to the pathophysiology of mental illness. Corticotropin-releasing factor (CRF) is a key neuropeptide controlling the HPA axis with a 41-amino acid sequence that is identical in humans and in rats ([Montecucchi et al. 1980](#)). CRF is produced in the paraventricular nucleus (PVN) of the hypothalamus, and once secreted into pituitary portal blood, it binds to G<sub>s</sub>-coupled receptors on cells in the pituitary to increase adenylate cyclase, cAMP-dependent protein kinase, and cytosolic calcium concentrations ([Lovejoy et al. 2014](#)). CRF is also capable of activating G<sub>q</sub>-, G<sub>i</sub>-, G<sub>o</sub>-, and G<sub>z</sub>-coupled receptors ([Grammatopoulos et al. 2001](#)). CRF receptors are classified into CRF1 and CRF2 ([Chen et al. 1993](#); [Liaw et al. 1996](#); [Lovejoy et al. 2014](#)). The CRF1A receptor is the dominant subtype in the brain and peripheral tissue, whereas the CRF1D receptor is thought to play a competing role against CRF1A, with CRF1B and CRF1C also being identified ([Hillhouse and Grammatopoulos 2006](#)). Although CRF2 receptors and their spliced variants CRF2A, CRF2B, and CRF2C are localized in the brain, they exist to a greater degree in peripheral tissue ([Hillhouse and Grammatopoulos 2006](#)).

**TABLE 2-2.     Selected peptides and their presumed relevance to psychiatric disorders and treatment**

Group	Potential clinical relevance
<b>Opioid and related peptides</b>	
Endorphin	Analgesia for chronic pain
Enkephalin	Analgesia

<b>Group</b>	<b>Potential clinical relevance</b>
Dynorphin	Analgesia
Nociceptin	Binds ORL1 receptor; increased pain perception
<b>Gut-derived peptides</b>	
Vasoactive intestinal peptide	Sexual behavior
Cholecystokinin	Anxiety/panic
Secretin	Brief reports of help with autism and transient antipsychotic properties
Somatostatin	Mood disorders and treatment
<b>Tachykinin peptides</b>	
Substance P (substance K)	Receptor is NK <sub>1</sub> , no efficacy shown for depression; inflammation
Neurotensin/neuromedin N	Analgesia, hypothermia; regulated by lithium, involved in dopamine signaling
<b>Pituitary peptides</b>	
Oxytocin	Affiliative, prosocial, bonding behavior; decreases fear; may help increase sociability in autism

<b>Group</b>	<b>Potential clinical relevance</b>
Vasopressin	Also called antidiuretic hormone; receptors are $V_{1a}$ , $V_{1b}$ , $V_2$ ; antagonists have anxiolytic, anti-aggression, and anti-irritability properties
Adrenocorticotrophic hormone	Dysregulated in mood disorders
Melanocyte-stimulating hormone	Antidepressant and anti-anxiety properties
<b>Hypothalamic-releasing factors</b>	
Corticotropin-releasing factor	Anxiety and fear
Thyrotropin-releasing factor	Potential antidepressant effects
<b>Others</b>	
Calcitonin gene-related peptide	Regulated by ECT and lithium
Angiotensin	Mood disorders, bipolar disorder
Leptin	Satiety signal; inhibits feeding drive
Cocaine- and amphetamine-related transcript	Drug addiction, eating disorders

<b>Group</b>	<b>Potential clinical relevance</b>
Galanin	Potentially relevant for Alzheimer's diagnosis and other cognitive disorders
Neuropeptide Y	Potential endogenous anxiolytic; regulated by antidepressants/lithium; reduced by early maternal separation; antagonists may decrease appetite
Orexin/hypocretin	Narcolepsy and other sleep abnormalities; eating disorders

*Note.* This table summarizes selected peptides and their presumed relevance for psychiatric disorders and their treatment; it is not meant to be an exhaustive listing of findings. It should also be noted that in some cases—for example, CRF (mood/anxiety), NPY and neurotensin (regulation by medications), oxytocin (affiliative behavior), and orexin (narcolepsy)—the data are quite convincing. In many of the other examples noted, the evidence must be considered preliminary but is, in our opinion, quite noteworthy and warrants further investigation. A discussion of these peptides is beyond the scope of this introductory chapter; nevertheless, readers are encouraged to explore the latest research in this rapidly evolving and exciting literature. ECT=electroconvulsive therapy.

Stressful life events and chronic stress can induce brain circuit changes that are thought to relate to the pathophysiology of some anxiety disorders and PTSD. Increased CRF secretion from the hypothalamus and adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland are associated with aberrant cortisol responses to stress. Depressed patients and suicide victims have elevations of CRF concentrations in the CSF, increased cerebrocortical CRF immunoreactivity, and decreased CRF1 receptor binding; furthermore, decreased CRF1 mRNA expression has been reported in postmortem brain tissue of suicide victims ([Sanders and Nemeroff 2016](#)). Although probes of HPA function, such as the dexamethasone/CRF suppression tests, indicate hyperactivity of the axis in depressed patients, it is largely a nonspecific finding and can occur in other psychiatric illnesses.

## Oxytocin and Vasopressin

Other brain-related peptides of interest to psychiatric illnesses that can be co-secreted with CRF from the hypothalamus are oxytocin and vasopressin, but treatments in psychiatry directed at these receptors have not yet received clinical use. Oxytocin and vasopressin are both 9-amino acid peptide hormones. Oxytocin has a 6-amino acid ring and a 3-amino acid tail with the ability to exert disulfide bonds that may relate to its neurophysiological mode of action. PVN and supraoptic nuclei of the hypothalamus are known to contain high levels of oxytocin, whereas vasopressin is localized in other cells in the hypothalamus; however, both can extend cellular processes into the posterior pituitary. These neuropeptides do not

function as traditional neurotransmitters, but rather permeate through neural tissue by volume transmission (Neumann and Landgraf 2012). It is noteworthy that oxytocin may modulate the amygdala and brain stem neurons to facilitate fear avoidance, whereas vasopressin may exert a role in PTSD (Carter 1998; Wentworth et al. 2013). Furthermore, oxytocin and vasopressin bind to distinct brain receptors that can be modulated by epigenetics (Ebstein et al. 2012). The oxytocin receptor is a GPCR located on 3p24-26, whereas three receptor subtypes have been identified for vasopressin (V1a, V1b, V2), with V1a and V1b currently associated with modulation of behaviors (Gimpl and Fahrenholz 2001).

## Opiates

*Opioids* are a family of peptides that occur endogenously in the brain (endorphins), as botanicals, or as drugs. POMC is a precursor protein characterized in the 1980s that gives rise to ACTH and a class of endogenous opiates called endorphins. POMC, proenkephalin-derived peptides, and prodynorphin-derived peptides yield opioid peptides on cleavage. Three opioid peptide families exist: enkephalins, endorphins, and dynorphins. POMC gene expression occurs in various areas of the brain and in other tissues. POMC has tissue- and cell-specific regulatory factors at every step from gene transcription to its posttranslational processing. Opioid peptides are stored in large dense-core vesicles and are co-released from neurons that usually contain a classic neurotransmitter agent (e.g., glutamate and norepinephrine). Opiorphin, an endogenously derived enkephalin that inactivates zinc ectopeptidase, has been

described as equal to morphine in the perception of pain (Wisner et al. 2006). Although opiates are widely associated with and used therapeutically in pain modulation, evidence indicates that dynorphin can actually activate bradykinin receptors and contribute to neuropathic pain (Altier and Zamponi 2006).

Opioids activate a variety of signal transduction processes, and different mechanisms in their regulation are in place for different cell types. The opioid receptors are GPCRs and exert their cellular effects by inhibiting adenylyl cyclase and regulating  $K^+$  and  $Ca^{2+}$  channels, via activation of  $G_i/G_o$ . There are three types of opioid receptors— $\mu$ ,  $\delta$ , and  $\kappa$ , each of which is further subclassified—in addition to opioid receptor like-1 (ORL1) receptor. These receptors are 7-transmembrane-spanning proteins that couple to inhibitory G-proteins or form homo- and heterodimeric complexes. They also alter calcium signaling through dissociation of  $G_{\beta\gamma}$  subunits and by reducing sensitivity to L-type, N-type, and P/Q-type channels. Also, numerous mechanisms have been described that allow opiates and synthetic opiate agents (i.e., morphine, fentanyl) to regulate receptor signaling, which can occur from the receptor being phosphorylated, desensitized, and internalized. Once the receptor is phosphorylated, recruitment of arrestins to the receptor occurs and can prime for sequestration. Interestingly, arrestin-3-deficient mice have tolerance to morphine and other  $\mu$  opioid receptor agents, whereas polymorphisms in *OPRM1* have been associated with opioid dependency. Intracellular cascades associated with opioid dependence and withdrawal have documented changes in mitogen-activated protein kinase (MAPK) and extracellular signal-regulated kinase 1/2 (ERK1/2) cascades, as well as

changes in transcription factors such as phosphorylated cAMP response element-binding protein (pCREB) and DeltaFosB, which have been linked to changes in the reward system ([Al-Hasani and Bruchas 2011](#)).

The continued study of the opioid system and the second-messenger changes brought about by the chronic administration of opioids has greatly facilitated our understanding of the molecular and cellular effects of drugs of abuse and the potential to develop novel therapeutics ([Nestler et al. 2015](#)). In response to the worldwide heroin epidemic, the medication buprenorphine, a partial agonist of the  $\mu$  opioid receptor and an antagonist of the  $\delta$  and  $\kappa$  opioid receptors, has become one of the most widely prescribed medications in the world to treat opioid use disorders, perhaps because it can be prescribed from an outpatient office setting.

## Conclusion

---

We have provided an overview of some fundamental aspects of neurotransmitters and brain receptor classes. For most psychiatrists, molecular and cellular biology have not traditionally played a major role in day-to-day clinical practice. However, new insights into the molecular and cellular basis of disease and drug action are being generated at an ever-increasing rate and will ultimately result in a transformation of our understanding and management of diseases. The “molecular medicine revolution” has used the power of sophisticated cellular and molecular biological methodologies to tackle many of society’s most devastating illnesses. The rate of progress

has been exciting indeed, and hundreds of GPCRs and their effectors have now been identified and characterized at the molecular and cellular levels. These efforts have allowed the study of a variety of human diseases that are caused by abnormalities in cell-to-cell communication. Studies of such diseases are offering unique insights into the physiological and pathophysiological functioning of many cellular transmembrane signaling pathways.

Psychiatry, like much of the rest of medicine, has entered a new and exciting age demarcated by the rapid advances and the promise of molecular and cellular biology and neuroimaging. There is a growing appreciation that severe psychiatric disorders arise from abnormalities in cellular plasticity cascades, leading to aberrant information processing in synapses and circuits mediating affective, cognitive, motoric, and neurovegetative functions. Thus, these illnesses can be best conceptualized as genetically influenced disorders of synapses and circuits rather than simply as deficits or excesses in individual neurotransmitters. Furthermore, many of these pathways play critical roles not only in synaptic and behavioral plasticity but also in long-term atrophic processes. Targeting these pathways in treatment may stabilize the underlying disease process by reducing the frequency and severity of the profound mood cycling that contributes to morbidity and mortality.

# CHAPTER 3

## Genetics and Genomics

Genetics and genomics are among the most important tools in modern psychiatric research. Spurred by the completion of the human genome sequence in 2001, the number of psychiatric genetic studies has increased dramatically in the last two decades ([Lander et al. 2001](#); [Venter et al. 2001](#)). In this chapter, we cover the basic methodologies and concepts and define key terms currently used in psychiatric genetics and genomics. [Figure 3-1](#) illustrates the genetic methods available in psychiatric research today. Our goal is to facilitate interpretation by physicians and scientists in the field of psychopharmacology of the avalanche of genetic and genomic data accumulating in the human neuropsychiatric literature. Throughout this

chapter, terms in common use in the genetics and genomics literature are italicized on first use and are defined.

## Epidemiological Basis for Genetic Contributions to Neurobehavioral Disorders

# Insights From Adoption and Twin Studies

Genetic epidemiological studies have established that most psychiatric disorders, as well as many nonpathological human behavioral traits, have a substantial genetic component. Investigations in genetic epidemiology have provided the scientific foundation for molecular genetic and genomic studies of human behavior and behavioral disorders (Kendler 1993, 2001; Plomin and Kosslyn 2001). Genetic epidemiology uses family, twin, and adoption studies to assess the contribution of familial, environmental, and genetic factors to a trait of interest. A family study uses a *pedigree* (a type of family tree) to establish whether a given disorder “runs in the family”; however, these studies cannot easily distinguish whether such familiarity is due to genetic or environmental factors. An everyday example of the distinction between *genetic* and *familial* (but environmental) traits is the difference between the ability to acquire language (a *genetic* trait that distinguishes humans from other species) and the native language spoken by a given person, which is *familial* but entirely environmentally determined.

Adoption and twin studies distinguish between genetic and environmental influences on traits by accounting for each separately. Adoption studies investigate whether an individual’s risk for a psychiatric disease depends on the mental health status of the biological or adoptive parents to disentangle genetic (i.e., similarity to biological parents, who have had little or no interaction with the adoptee) from environmental influence (i.e., similarity to adoptive parents, who have provided the adoptee with his or her family and

social environment) ([Cadoret 1986](#); [Tienari and Wynne 1994](#); [Tienari et al. 2004](#)). Practical, ethical, and legal obstacles make large-scale adoption studies very difficult to conduct. Twin studies, while also quite challenging, are more tractable, and large twin registries are now available globally ([Busjahn 2002](#)). These studies have provided the bulk of the strong evidence supporting genetic contributions to psychiatric disorders and human behavioral traits.

In twin studies, one determines the probability of one twin being affected with a given trait or disorder, given the affectation status of the co-twin. This degree of correlation between twins for the investigated trait is then compared between monozygotic (MZ) and dizygotic (DZ) twins to gain information on the degree of genetic and environmental influence on a certain trait. MZ twins result from a separation of the zygote to yield two genetically identical embryos. DZ twins result from the separate fertilization of two eggs in the same pregnancy. DZ twins thus share on average only 50% of their genes, similar to siblings born in separate pregnancies. Although neither the pre- nor the postnatal environments of twins are perfectly identical, to a first approximation MZ and DZ twins are equally correlated for relevant environmental exposures ([Kendler and Gardner 1998](#)). The trait correlation between MZ and DZ twins therefore allows estimation of the degree to which additive genetic effects or shared or individual-specific environmental effects contribute to the likelihood of a given trait. [Figure 3-2](#) summarizes the relative contributions of each factor, estimated from patterns of correlation between MZ and DZ twins (for a methodological review of this topic, see [Bulik et al. 2000](#)).

**FIGURE 3-2.** Patterns of intrapair correlations and source of variance implied.

Intrapair correlations around zero imply effects of individual-specific environment. Equal intrapair correlations that are greater than zero for monozygotic (MZ) and dizygotic (DZ) twins imply effects of shared environment. Correlations for MZ twins that are twice as great as those for DZ twins imply additive genetic effects. Correlations for MZ twins that are greater than—but not twice as great as—those for DZ twins imply additive genetic effects and shared environment effects. The correlations of less than 1.0 in the

last three examples are likely mediated by individual-specific environment effects.

Twin studies have firmly established important genetic contributions for all psychiatric disorders, with *heritability* estimates (i.e., the proportion of risk for a disorder attributable to the additive effects of genes) ranging from 30% to 80% for most common psychiatric disorders (Table 3-1).

In more recent research, twin studies are being used to investigate the influence of *epigenetics*. Epigenetics refers to the chemical modification of genes without alteration of the genome sequence. These modifications determine

whether a given gene is expressed (switched on) or not expressed (switched off) and are driven by the DNA sequence together with environmental stimuli. Large-scale twin studies are helping to reveal the contribution of epigenetic alterations in psychiatric disorders by allowing investigators to disentangle genetic versus environmental contributions in MZ and DZ twins.

Genetic epidemiology also can contribute to exploration of more complex questions, such as whether genetic risk factors are shared among different psychiatric disorders and between sexes and whether these genetic risk factors can moderate the effects of environmental risk factors ([Kendler 2001](#)) and can therefore lead the design of follow-up molecular genetic studies. For example, a twin study has suggested that genetic risk factors for major depressive disorder could in part act by increasing vulnerability to stressful life events ([Kendler 1995](#)). This suggestion has been corroborated by findings from a number of gene  $\times$  environment (G $\times$ E) interaction studies, including studies confirming the interaction of functional alleles of the locus encoding the serotonin transporter protein with stressful life events to predict risk of depression ([Caspi et al. 2003](#); [Karg et al. 2011](#); [Kaufman et al. 2004](#); [Kendler et al. 2005](#); [Sjöberg et al. 2006](#); [Surtees et al. 2006](#); [Wilhelm et al. 2006](#)) and the interaction of genetic polymorphisms at the gene for FK506 binding protein 5 (*FKBP5*) with childhood abuse to predict risk of posttraumatic stress disorder (PTSD; [Zannas et al. 2016](#)). Genetic epidemiological studies—and, more specifically, twin studies—therefore have been an important foundation of psychiatric genetics and are likely to continue to contribute more elaborate disease models for future molecular genetic analysis. The major limitation of these studies, however, is that the estimated

heritability with twin studies is only an estimate of the aggregate genetic effect. Heritability does not give any information about the contributions of specific genes to risk for a disorder. The answers to those questions, which will require deployment of an array of molecular genetic techniques, will ultimately shed light on the developmental neurobiology underlying psychiatric illness.

## Psychiatric Disorders Are Complex Genetic Disorders

Genetic epidemiological studies have established that psychiatric disorders are likely not single-gene disorders inherited in a *Mendelian* fashion (i.e., in a clear recessive, dominant, or X-linked fashion), although rare families in which psychiatric phenotypes are inherited this way have been reported ([Brunner et al. 1993](#)). A genetic disorder can be complex for several reasons:

- *Incomplete penetrance*: not every person carrying the disease allele(s) becomes ill.
- *Phenocopy occurrence*: nonheritable traits caused by environmental factors can resemble traits caused by a genetic mutation.
- *Locus heterogeneity*: variants in different genes can lead to similar or identical disease phenotypes.
- *Allelic heterogeneity*: different patterns of variation within the same gene or genes can lead to similar or identical disease phenotypes.
- *Polygenic inheritance*: additive or interactive effects of variation at multiple genes (i.e., *epistatic effects*) are necessary for an illness to manifest.

- *Gene–environment interaction*: a disorder manifests in response to environmental factors only in the context of predisposing genetic variants. An extreme example of such interaction is phenylketonuria, in which exposure to dietary phenylalanine causes severe neurobehavioral impairment in individuals carrying two mutant copies of the locus encoding phenylalanine hydroxylase; limitation of dietary phenylalanine prevents the neurobehavioral disorder.
- *High frequency of the disorder and the predisposing alleles*. It appears increasingly likely that common disorders such as schizophrenia, diabetes mellitus, stroke, and hypertension represent final common outcomes of a variety of combinations of environmental and genetic predisposing factors. Thus, two individuals, even within the same family, might manifest clinically indistinguishable disorders for different reasons.
- *Other genetic mechanisms of inheritance*: alternative genetic mechanisms—for example, mitochondrial inheritance or alteration of the genome across generations, such as occurs in trinucleotide-repeat-expansion disorders (e.g., Huntington’s disease and fragile X syndrome) or in epigenetic disorders—may be involved in producing a disorder. Epigenetic disorders result from alterations in the genetic material that do not involve changes in the base-pair sequence of DNA. Examples of epigenetic disease include the imprinted disorders Angelman syndrome and Prader-Willi syndrome, in which parent of origin–dependent chemical modification of DNA produces different phenotypic outcomes from the same chromosomal deletion.

From the cumulative evidence of psychiatric genetic studies thus far, one can conclude that psychiatric disorders deviate from the “common disease, common variant” hypothesis and instead fit a polygenic mode of inheritance, with many polymorphic loci contributing to these disorders ([Cross-Disorder Group of the Psychiatric Genomics Consortium 2013](#); [Geschwind and Flint 2015](#); [Smoller 2016](#); [Sullivan et al. 2012](#)), as has been found in studies of unipolar depression (i.e., major depressive disorder) ([Johansson et al. 2001](#); [Kendler et al. 2006](#); [Ripke et al. 2013b](#)), bipolar disorder ([Blackwood and Muir 2001](#); [Psychiatric GWAS Consortium Bipolar Disorder Working Group 2011](#); [Ruderfer et al. 2014](#)), schizophrenia ([S.H. Lee et al. 2012](#); [Purcell et al. 2009](#); [Ripke et al. 2013a](#); [Ruderfer et al. 2014](#)), and autism spectrum disorder ([Carayol et al. 2014](#); [Folstein and Rosen-Sheidley 2001](#); [Gillis and Rouleau 2011](#)). For example, the largest genomewide association analysis to date identified 108 schizophrenia loci ([Ruderfer et al. 2014](#)), supporting the hypothesis that locus heterogeneity is an important factor in schizophrenia. Thus, [Bleuler \(1951\)](#) appears to have been correct when he referred to dementia praecox as “the group of schizophrenias.”

As already noted, susceptibility genes are likely to interact with environment, gender, and other genes, making the search for “genes for psychiatric disorders” even more complex ([Kendler and Greenspan 2006](#)). Twin studies have produced evidence that genetic interactions with stressful life events predict major depressive disorder ([Kendler et al. 1995a](#)) and that genetic interactions with early rearing environment predict schizophrenia, conduct disorder, and drug abuse ([Cadoret et al. 1995a, 1995b](#); [Tienari et al. 2004](#)). A key series of studies by [Caspi and](#)

[Moffitt \(2006\)](#) enriched our understanding of G×E interactions and led to increased momentum in research. Although most G×E studies look into detrimental environmental factors, their scope also should encompass positive or protective environmental factors ([Klengel and Binder 2015](#)). Furthermore, gender-specific predisposing genes for psychiatric disorders are likely. Data from twin studies suggest that the combined genetic factors conferring risk for major depressive disorder, phobias, and alcoholism may differ in some respects for men and women ([Kendler and Prescott 1999](#); [Kendler and Walsh 1995](#); [Kendler et al. 2001a, 2002, 2006](#); [Prescott and Kendler 2000](#); [Prescott et al. 2000](#)), and this theory has been supported in molecular genetic studies by the identification of gender-specific loci for anxiety and major depressive disorder, for example ([Quast et al. 2014](#); [Unschuld et al. 2010](#)). Finally, gene–gene interactions also may be relevant for these disorders ([Risch 1990](#)) but have not been studied in detail thus far.

## Genetic Modifiers of Response to Drug Treatment

In contrast to the profusion of genetic epidemiological studies on disease susceptibility, genetic epidemiological studies on responses to psychotropic drugs are rare. Some evidence from family studies suggests an important contribution of genetic factors in antidepressant response. Already in the early 1960s, studies on the effects of tricyclic antidepressants (TCAs) and later on lithium ([Grof and Alda 2000](#); [Smeraldi et al. 1984](#)) in patients and their first-degree relatives suggested that response to these drugs

was similar among family members ([Angst 1961](#); [Pare et al. 1962](#)). [O'Reilly et al. \(1994\)](#) reported a familial aggregation of response to tranylcypromine, a monoamine oxidase inhibitor, in a large family with major depressive disorder. These initial reports were followed by only a few systematic studies. [Franchini et al. \(1998\)](#) indicated a possible genetic basis of response to the selective serotonin reuptake inhibitor (SSRI) fluvoxamine in 45 pairs of relatives. In light of these data, some groups have used or proposed to use response to certain antidepressant drugs or mood stabilizers as an additional phenotype in classical linkage analyses for mood disorders in the hope of identifying genetically more homogeneous families ([Serretti et al. 1998](#); [Turecki et al. 2001](#)).

Nonetheless, family studies supporting a genetic basis for response to psychotropic drugs are sparse, certainly reflecting the extreme difficulties inherent in conducting well-controlled family studies of therapeutic response to medications. It has been proposed that genetic modifiers of response to treatment to psychotropic drugs may be easier to detect than associations with disease susceptibility, because the genetic contribution to these traits may be less complex ([Weinshilboum 2003](#)). The strongest molecular data exist for lithium response. The response of bipolar patients to lithium treatment has been associated with genetic variations with genomewide significance ([Alda 2015](#); [Chen et al. 2014](#); [Hou et al. 2016](#)).

Mounting evidence suggests that in addition to genetic variation, epigenetic mechanisms underlie some of the therapeutic effects of common psychotropic drugs ([Boks 2014](#)), including antidepressants ([Menke and Binder 2014](#)), valproic acid, and lithium ([Boyadjieva and Varadinova 2012](#); [R.S. Lee et al. 2015](#)).

# Human Genetic Variation

---

As mentioned previously, genetic epidemiological studies can indicate the presence of an aggregate genetic effect but cannot identify which type and how many variations contribute to the effect. A discrepancy exists between heritability estimates from family studies and those from population cohorts. For example, heritability estimates for schizophrenia from twin studies average about 0.8 ([Sullivan et al. 2003](#)), whereas population estimates are always lower, about 0.65 ([Lichtenstein et al. 2009](#)). In this section, we offer an overview of the types of variation that occur in the human genome and provide examples illustrating the implications of each variation type for psychiatric disorders.

## Variation on a Chromosomal Scale

### Variation in Chromosomal Number

The human genome has approximately 3 billion bases that are distributed over 23 chromosome pairs, with 22 pairs of autosomes and 1 pair of sex chromosomes, X and Y. The most obvious genetic variations can be observed at the light microscope level in the karyotype. This approach visualizes metaphase chromosomes using histological procedures, allowing identification of each specific pair of chromosomes and variations in the total number of chromosomes, such as unisomies and trisomies. Several of the known variations of total chromosome number have an associated psychiatric phenotype. For example, Down syndrome is a complex neurodevelopmental disorder that results in variable levels of intellectual disability and, in old age, dementia strikingly

similar to Alzheimer's disease ([Visootsak and Sherman 2007](#)). Down syndrome results from *trisomy 21* (i.e., inheritance of three copies of chromosome 21, caused by meiotic nondisjunction during oogenesis). Turner syndrome, in which the person has only a single X chromosome (i.e., an XO karyotype), is associated with nonverbal learning disabilities, particularly in arithmetic, certain visuospatial skills, and processing speed ([Sybert and McCauley 2004](#)).

## Translocations

Karyotypic examination and other cytogenetic techniques such as fluorescent in situ hybridization (FISH) can detect additional large-scale chromosomal abnormalities, such as translocations, deletions, or duplications of large regions of chromosomes. In a large Scottish pedigree, a balanced translocation between chromosomes 1 and 11 appears to be causally linked to a series of major psychiatric disorders, including schizophrenia, bipolar disorder, recurrent major depressive disorder, and conduct disorder ([St Clair et al. 1990](#)). This *balanced translocation* (which exchanged parts of chromosome 1 with parts of chromosome 11 to produce two abnormal chromosomes but no net loss of chromosomal material) disrupts two genes at the translocation breakpoint on chromosome 1, termed *disrupted in schizophrenia* (DISC) 1 and 2 ([Millar et al. 2000, 2001](#)). Subsequent molecular analysis has provided strong evidence that variation in *DISC1* can alter the risk for schizophrenia ([Porteous et al. 2006](#)). Although most still consider the *DISC1* translocation to be a confirmed schizophrenia risk factor ([Porteous et al. 2014](#)), this is hotly debated because of concerns about the standard of the evidence ([Sullivan 2013](#)).

## Deletions

Microdeletions occurring on the long arm of chromosome 22 have received considerable attention as cytogenetic risk factors for the development of schizophrenia ([Karayiorgou and Gogos 2004](#)). The 22q11 deletion syndrome, in which 1.5–3.0 million base pairs (bp) of DNA are missing on one copy of 22q, includes a spectrum of disorders affecting structures associated with development of the fourth branchial arch and migration of neural crest cells (e.g., the great vessels of the heart, the oropharynx, the facial midline, the thymus, the parathyroid glands). Originally described as distinct disease syndromes prior to the elucidation of their common molecular etiology, 22q11 deletion syndrome includes velocardiofacial syndrome (VCFS), DiGeorge syndrome, and conotruncal anomaly face syndrome. Following an initial report of early-onset psychosis in patients with VCFS ([Shprintzen et al. 1992](#)), [Pulver et al. \(1994\)](#) examined psychiatric symptoms in adults with VCFS and in a cohort of patients ascertained for schizophrenia ([Karayiorgou et al. 1995](#)). The latter study identified two previously undiagnosed cases in 200 patients, verified by FISH to carry 22q11 deletions ([Karayiorgou et al. 1995](#)). There is a reported 10–20 times higher prevalence of the 22q11 deletion in patients with schizophrenia ([Rees et al. 2014b](#)), and duplications of 22q11.2 might prove protective ([Rees et al. 2014a](#)). The deletion is thought to be one of the strongest risk factors for psychosis ([Schneider et al. 2014](#)), with early cognitive decline being a strong indicator of subsequent psychosis development ([Vorstman et al. 2015](#)).

## Duplications

Duplications of the long arm of chromosome 15 (15q11-13) are the most frequent cytogenetic anomalies in autism spectrum disorder, occurring in approximately 1%-2% of cases ([Cook 2001](#)). This duplication syndrome cannot be clinically differentiated from idiopathic autism ([Veenstra-VanderWeele and Cook 2004](#)), indicating that a complete workup of autism spectrum disorder should include testing for this cytogenetic abnormality as well as several others ([Martin and Ledbetter 2007](#)). Interestingly, deletion of this same region of 15q is associated with Angelman syndrome when the deletion occurs on the maternal copy of chromosome 15 and with Prader-Willi syndrome when the deletion occurs on the paternal chromosome (or, more rarely, when two maternal copies of chromosome 15 are present and the paternal chromosome is missing entirely, a condition known as *maternal disomy*). Both syndromes manifest as quite distinct but dramatic neurobehavioral disorders ([Nicholls and Knepper 2001](#); [Vogels and Fryns 2002](#)). Induced pluripotent stem cells are now being used to model copy number variations for individual patients. These models have the potential to help explain the underlying mechanisms of psychopathologies. For example, induced pluripotent stem cells taken from patients with 15q11 copy deletion show deficits in adherens junctions and apical polarity. The study pinpointed a haploinsufficiency at *CYFIP1*, one of the genes within the larger deletion ([Yoon et al. 2014](#)).

## Molecular Variation in the Genome

Most genetic and genomic studies in neuropsychiatry conducted to date have examined variation at the molecular

level, which would be undetectable with methods appropriate for the chromosomal-level variation described earlier. To introduce this section, we provide basic definitions of common terms.

## **Definition of Alleles, Genotypes, and Haplotypes**

Familiarity with the terms *allele*, *genotype*, and *haplotype* is fundamental to understanding the various types of polymorphisms discussed later in this section. An *allele* is a variation in DNA sequence that occurs at a particular *polymorphic* site on one chromosome. Every individual with a normal set of chromosomes has two alleles for each polymorphism on the *autosomes* (nonsex chromosomes, numbers 1-22). On the sex chromosomes, men have only one allele each for all polymorphisms located on the X and Y chromosome, whereas women carry two copies of each X-linked allele. A *genotype* is the combined description for the variation at a particular corresponding point on homologous chromosomes and is expressed as two alleles. When the alleles on both chromosomes are the same, it is a *homozygous* genotype. When the alleles differ, it is a *heterozygous* genotype. A *haplotype*, a term derived from the abbreviation of “haploid genotype,” is the sequence of alleles along an adjacent series of polymorphic sites on a single chromosome. When genotypic data are available from three generations, haplotypes in the third generation can be unambiguously deduced. In the absence of sufficient family-based data (e.g., in case-control studies of unrelated individuals), some haplotypes are ambiguous because the combination of genotypes at the polymorphic sites under study can be explained by more than one set of possible

chromosomal arrangements of the component alleles. In these cases, methods such as estimation maximization can be used to infer the most likely haplotype ([Hawley and Kidd 1995](#); [Long et al. 1995](#)).

## Copy Number Variation

Genome-scale investigations enabled by the sequencing of the human genome and the advent of array-based comparative genomic hybridization have identified a previously unappreciated form of polymorphic variation in the human genome: chromosomal regions containing one or more genes can sometimes be deleted or, alternatively, occur in multiple copies, with the number of copies differing among individuals ([Nadeau and Lee 2006](#); [Sebat et al. 2004](#)). Such *copy number variants* (CNVs) occur normally in human populations, and a map of such variants is available ([Zarrei et al. 2015](#)). CNVs have been associated with marked differences in gene expression ([Stranger et al. 2007](#)), and they also can be associated with predisposition to disease, including neurobehavioral disorders ([Sebat et al. 2007](#)).

CNV analysis in schizophrenia has shown that rare deletions and duplications increase risk ([International Schizophrenia Consortium 2008](#)) and has implicated the involvement of genes in neurodevelopmental pathways ([Walsh et al. 2008](#)) and postsynaptic signaling complexes ([Kirov et al. 2012](#)). CNVs also have been found to be associated with autism spectrum disorder ([Marshall et al. 2008](#)). Indeed, CNV studies have now shown the same genes to be disrupted or affected in schizophrenia, attention-deficit/hyperactivity disorder (ADHD), and autism spectrum disorder. This broad phenotypic spectrum suggests that these CNVs generally impair

neurodevelopment ([Rosenfeld et al. 2010](#)). Interestingly, a recent study in children with ADHD showed that in comparison with control subjects, children with large, rare CNVs had lower polygenic risk scores, whereas those without such CNVs had higher polygenic risk scores ([Martin et al. 2015](#)), indicating that risk is conferred by either rare (for lower scores) or common (for higher scores) variants. (Polygenic risk scores are discussed later in this chapter, in the section titled “Use of GWAS Data.”)

Copy number variation of the cytochrome P450 (CYP) gene *CYP2D6*, which is important for the metabolism of many antidepressants, antipsychotics, and mood stabilizers ([Kirchheiner et al. 2004](#)), provides a prominent example of the importance of CNVs to pharmacogenetics. The presence in the genome of copy number variation at the *CYP2D* locus was inferred through biochemical-genetic studies predating the molecular era and was subsequently confirmed by molecular studies. The reported range of copy numbers of *CYP2D6* is from 0 to 13. The number of functional *CYP2D6* gene copies directly correlates with plasma levels of metabolized drugs, such as the TCA nortriptyline ([Bertilsson et al. 2002](#)). In fact, the first trial examining the cost-effectiveness of screening for *CYP2D6* in patients initiating treatment with the antidepressant nortriptyline or venlafaxine has begun ([Berm et al. 2015](#)).

## Insertion/Deletion Polymorphisms

Microscopic insertions and deletions (much smaller than CNVs—on the order of one to hundreds of bp) are another important type of genetic variation. The most famous insertion/deletion polymorphism in psychiatric genetics is a common functional polymorphism in the promoter region of the serotonin transporter gene *SLC6A4*, referred to as the

serotonin transporter-linked promoter region (5HTTLPR). It consists of a repetitive region containing 16 imperfect repeat units of 22 bp, located approximately 1,000 bp upstream of the transcriptional start site (Heils et al. 1996; Lesch et al. 1996). The 5HTTLPR is polymorphic because of the insertion/deletion of the repeat units 6-8 (of the 16 repeats), which produces a short (S) allele that is 44 bp shorter than the long (L) allele. Although the 5HTTLPR was originally described as biallelic, rare (<5%) very-long and extra-long alleles have been described in Japanese and African Americans (Gelernter et al. 1999). Numerous additional variants within the repetitive region also occur (Nakamura et al. 2000). Thus, although most studies continue to treat this complex region as biallelic, this is an oversimplification that may be hiding additional genetic information.

The 5HTTLPR has been associated with altered basal activity of the transporter, most likely related to differential transcriptional activity (Heils et al. 1996; Lesch et al. 1996). The long variant (L allele) of this polymorphism has been shown to lead to a higher serotonin reuptake by the transporter in vitro. It is also noteworthy that the function of this insertion/deletion polymorphism may be influenced by a *single nucleotide polymorphism* (SNP) that occurs with the L allele (Hu et al. 2006). However, a positron emission tomography (PET) study was unable to identify differences in serotonin transporter binding potential by the 5HTTLPR genotype, even when including the information of the additional SNP, in healthy control subjects or patients with major depressive disorder (Parsey et al. 2006). This polymorphism has shown associations with a multitude of psychiatric disorders and related phenotypes. The best-established associations are with response to SSRI

antidepressants ([Porcelli et al. 2012](#); [Serretti et al. 2007](#)) and with moderation of the influence of life events on risk of depression ([Caspi et al. 2003](#)), although the latter finding remains controversial ([Karg et al. 2011](#); [Kaufman et al. 2004](#); [Kendler et al. 2005](#); [Munafò et al. 2009](#); [Risch et al. 2009](#); [Surtees et al. 2006](#); [Wilhelm et al. 2006](#); [Zalsman et al. 2006](#)).

## Microsatellites: STRs and VNTRs

---

A very important class of polymorphisms, on which molecular linkage studies and some association studies were based until very recently, is *microsatellite* markers, also called *short tandem repeats* (STRs) or *variable number of tandem repeats* (VNTRs). The polymorphisms consist of simple sequences, such as guanine-thymine (GT) or guanine-adenine-thymine-adenine (GATA), that are repeated a variable number of times. An individual thus may have five GT repeats at a specific locus on one chromosome and seven such repeats on the other. When these regions are amplified by *polymerase chain reaction* (PCR), a technique for producing many copies of a specific small portion of the genome based on DNA polymerase activity directed by specific DNA sequences, the difference in number of repeats results in differences in the length of the amplified fragments (a difference of 4 bp in the present example), allowing efficient genotyping of these polymorphisms by gel electrophoresis, which separates DNA fragments according to length. About 30,000 of these polymorphisms are now known in the human genome ([Kawashima et al. 2006](#); [Tamiya et al. 2005](#)), and they have

served as markers for genomewide linkage analysis (see “Linkage Studies” subsection later in this chapter for more detail).

VNTRs not only serve as genetic markers for linkage analysis but also may produce functional variation within genes. An important example of such functional variation is a VNTR in the 3′ untranslated region of the dopamine transporter (DAT) gene *SLC6A3*. The repeat element consists of a 40-bp sequence that can occur with 3–11 repeats, with 9 or 10 repeats being the most common ([Vandenbergh et al. 1992](#)). Different effects of the 9 or 10 repeats on gene expression and DAT binding using single photon emission computed tomography (SPECT) in humans have been reported, although the direction of these differences is controversial ([Greenwood and Kelsoe 2003](#); [Inoue-Murayama et al. 2002](#); [Martinez et al. 2001](#); [Mill et al. 2002, 2005](#); [van Dyck et al. 2005](#); [VanNess et al. 2005](#)), with the 9- and the 10-repeat alleles respectively associated with higher expression of the DAT gene and higher DAT binding in different studies. Another example of a functional VNTR (48-bp repeat) is a polymorphism in the third exon of the *DRD4* locus (the locus encoding the dopamine D<sub>4</sub> receptor), which results in a variable number of glutamine residues in the third intracellular loop of the dopamine D<sub>4</sub> receptor protein ([Van Tol et al. 1992](#)). The allelomorphic proteins differ in their ligand-binding affinities, but all couple to G proteins ([Van Tol et al. 1992](#)). Both polymorphisms have been associated with a multitude of behavioral and psychiatric phenotypes ([Gatt et al. 2015](#)), including bipolar disorder ([Seifuddin et al. 2012](#)), ADHD ([Wu et al. 2012](#)), and depression ([Opmeer et al. 2010](#)). In PET studies, the 9- or 10-repeat alleles have been

associated with decreased in vivo DAT activity (Faraone et al. 2014).

## Single Nucleotide Polymorphisms

The polymorphisms that have revolutionized (not only) psychiatric genetics are SNPs (Altshuler et al. 2000; Sachidanandam et al. 2001). SNPs consist of a single-base difference at a particular site in the genome—in two-thirds of the cases, a cytosine (C)-to-thymine (T) exchange. Although theoretically the presence of all four different bases at an SNP is possible, the vast majority of SNPs have only two alleles, but SNPs with three or four different alleles occasionally have been reported. As of September 2016, around 150 million human SNPs had been catalogued in public databases (such as dbSNP: e.g., [www.ncbi.nlm.nih.gov/projects/SNP](http://www.ncbi.nlm.nih.gov/projects/SNP)). SNPs are so far the most common type of genetic variation and may represent up to 90% of all genetic variations (although this estimate may need revision as knowledge about CNVs accumulates). Besides being very common (SNPs occur, on average, every 300 bases), they are also amenable to high-throughput genotyping methods (Kim and Misra 2007; Kwok 2000). Because SNPs are common (essentially every gene of interest has several known SNPs) and cheap to genotype, they are the markers of choice for complex trait genetic association studies.

Besides serving as genetic markers for chromosomal loci in association studies, SNPs also can have functional relevance themselves. SNPs in regulatory regions can alter the transcriptional regulation of a gene, SNPs in regions relevant for mRNA splicing can alter splice sites, and SNPs in protein-coding exons can encode differences in primary amino acid sequence. Interestingly, when one considers the

occurrence of SNPs across the genome, one observes that SNPs are most dense in intergenic and intronic regions but scarcer in putative regulatory regions and exons, suggesting selection against putatively functional variants ([Altshuler et al. 2000](#); [Sachidanandam et al. 2001](#)). Within exons, SNPs that will not cause an amino acid exchange due to the degenerate code are called *synonymous* SNPs as opposed to *nonsynonymous* SNPs, which lead to amino acid substitution. One nonsynonymous SNP that repeatedly has been associated with psychiatric phenotypes is a valine (Val)-to-methionine (Met) exchange at amino acid position 108/158 in the soluble or membrane-bound form of the catechol-*O*-methyltransferase (COMT) peptide sequence resulting from a guanine (G)-to-adenine (A) exchange at position 472 of exon 4. This amino acid exchange dramatically affects the temperature lability of this enzyme, with the Met allelomorphic protein having only one-fourth of the enzyme activity at 37°C of the Val allelomorph ([Lachman et al. 1996](#); [Lotta et al. 1995](#)). It is presumed that individuals with the Val/Val genotype have a more rapid inactivation of centrally released dopamine than individuals with the other genotypes, following an additive genetic model. This polymorphism seems to affect dopamine transmission—particularly in the frontal cortex, where expression of the dopamine transporter protein is relatively low—and has been associated with differences in executive cognition and functional activity of the prefrontal cortex during working-memory tasks ([Egan et al. 2001](#); [Goldberg et al. 2003](#); [Joober et al. 2002](#); [Mattay et al. 2003](#)). Although it was hypothesized that this polymorphism also could alter the risk for schizophrenia (particularly because COMT resides in the 22q11 region, the deletion of which has been associated with schizophrenia), larger association

studies and meta-analyses do not fully support that conclusion ([Fan et al. 2005](#); [Farrell et al. 2015](#); [Okochi et al. 2009](#)).

## Identification of Risk Loci for Psychiatric Disorders

---

In the following subsections, we focus on methods for identifying genetic psychiatric disease risk.

### Cytogenetic Studies

Disruption of chromosomal integrity by rare events such as balanced translocations has facilitated gene discovery in a variety of diseases and holds significant promise for similar applications in psychiatric illness ([Pickard et al. 2005](#)). Advances in techniques such as chromosome painting, high-resolution FISH, and, most recently, genomewide analysis of CNVs using microarrays have made it possible to identify disruptions in chromosomal architecture to single-base resolution, thus facilitating identification of specific genes in families cosegregating mental illness and cytogenetic abnormalities. Such data then may be used to generate testable hypotheses about the role of a particular gene in disease pathophysiology. The *DISC1* and *DISC2* genes provide clear examples of specific genes implicated in mental illness following their discovery through careful molecular analysis of a cytogenetic anomaly. Because much more work has been published on *DISC1*, we focus on that locus here.

As noted previously, *DISC1* was initially identified by cytogenetic studies in which a large Scottish family with numerous relatives affected by major psychiatric illness were shown to carry a balanced (1;11) (q42;q14.3) translocation that cosegregates with the presence of psychiatric illness. Linkage analysis using the psychiatric diagnosis as a phenotype and the translocation as a genetic marker yielded highly significant evidence supporting linkage of the translocation to psychiatric illness, and particularly to schizophrenia ([Blackwood et al. 2001](#); [St Clair et al. 1990](#)). The translocation was shown to disrupt *DISC1* and *DISC2* on chromosome 1 ([Millar et al. 2000, 2001](#)), whereas no known genes were disrupted on chromosome 11. *DISC1* was shown to encode a novel protein, with no known related proteins, that subsequently has been shown to play important roles in several key neuronal functions, including axonal transport and regulation of G-protein-mediated intracellular signaling ([Porteous et al. 2006, 2014](#)). Studies in induced pluripotent stem cell-derived forebrain neurons suggest that *DISC1* mutations are associated with disrupted synaptic vesicle release ([Wen et al. 2014](#)).

## Linkage Studies

In the 1980s and 1990s, many genes for Mendelian disorders were successfully identified with linkage analysis in large families. Linkage relies on the principle that, on average, chromosomes from parents differ from those of offspring by only one meiotic crossover event. During *meiosis*, the cell divisions that produce gametes by reducing the diploid genome (i.e., two chromosomes of each

pair per cell) to a haploid genome (one copy of each chromosome per spermatocyte or oocyte), homologous grandparental chromosomes (i.e., paternal and maternal to the parents of the offspring of interest), make physical contact and exchange homologous regions (referred to as *crossing over*) to give rise to a new set of chromosomes in which each gametic chromosome is a mix of grandparental sequences. This crossing-over process produces *recombination* that can then be tracked with molecular markers to delineate the ancestral origin of each chromosomal region in the offspring.

Classically, linkage studies use from several hundred to a few thousand microsatellite markers, evenly spaced across the genome. These markers are then genotyped in large families in which the disease of interest is common. To identify positions in the genome that may be involved in the disease, one tracks whether marker alleles are inherited by affected relatives more often than would be expected by chance (i.e., linkage tests whether a particular chromosomal region *cosegregates* with the disease). A quantitative measure of the likelihood of a particular pattern of marker-disease cosegregation is the *logarithm of odds (LOD) score*. As the name implies, the LOD score is logarithmic, with LOD=1 corresponding to 1:10 odds, LOD=2 to 1:100 odds, and so forth. Because of the high a priori probability that a given region is *not* linked to a given phenotype, a LOD score of 3.3 or greater is usually required before significant linkage is accepted ([Lander and Schork 1994](#)). The results of linkage analyses are usually presented as plots of LOD scores at each marker, which are arranged in their known order across individual chromosomes or the entire genome. These plots show a pattern of peaks and valleys. Linkage peaks identify

chromosomal regions (i.e., loci) where the LOD score is high, suggesting a high probability that a disease-linked variant resides nearby. Because of the spacing of the markers and their multiallelic properties, the identified regions are usually large, comprising up to tens of mega bases and harboring dozens of genes (which are then referred to as *positional candidates* because they reside under the linkage peak). Linkage peaks need to be followed up with additional *fine mapping* using denser marker maps, including SNPs, to hone in on the candidate gene(s) of interest.

Classical linkage approaches have been very successful in identifying monogenic diseases that follow clear, simple patterns of inheritance, but they have been far less successful in complex psychiatric disease. Parametric linkage analysis requires specification of an inheritance model (e.g., recessive or dominant), information we do not have for psychiatric disorders, as they clearly do not follow Mendelian inheritance. In addition, each family may have a different pattern of inheritance, so that specifying one model for several pedigrees may decrease the power to detect a signal in some of the families. Nonparametric linkage analyses that are mode-of-inheritance independent have been developed to address this problem. Also, linkage analysis requires that each person in a pedigree be designated as either affected or unaffected, so one must decide, for example, in which category to place individuals with a single major depressive episode in a bipolar pedigree. Linkage analysis studies therefore often run several different models and also may use different definitions of affected status and then report the best LOD score, but here the threshold for significance also has to be adjusted for additional multiple testing, so that even higher

LOD scores are required for statistical significance. Linkage analyses in psychiatric disorders are further complicated by the fact that they explore complex psychiatric diseases, with likely multiple (possibly additive or interacting) susceptibility genes and a strong environmental component, all of which cannot be modeled easily in these analyses. It is therefore not surprising that linkage analyses have yielded inconsistent results in the past.

## Association Studies

Association studies are usually performed in case-control studies of unrelated individuals. In such studies, allele frequencies of markers are compared between a case and a control population. Association has been shown to have more power than linkage studies to detect susceptibility genes that exert only a small effect on disease risk ([Risch and Merikangas 1996](#)). Considering the strong evidence supporting complex inheritance for most psychiatric disorders, it appears that association studies are the optimal study design to identify and/or test candidate genes for these disorders. To help interpret genetic association studies, we first want to introduce several key concepts, which are important for the design and understanding of association studies.

### Linkage Disequilibrium

Association studies rely on the principle that even unrelated individuals share very small stretches of chromosomal DNA derived from a distant common ancestor. In the case of a disease-predisposing mutation, some proportion of ill individuals will share that mutation arising from an original

common ancestor. As the variant is passed down from generation to generation, meiotic recombination events will shrink the size of the initial piece of ancestral chromosome that is inherited together with the disease mutation. On these small ancestral stretches of chromosome (perhaps several thousand to several hundred thousand bp in length), nonfunctional “marker” polymorphisms close to the disease mutation will “ride” through generations together with the disease variant. Such markers (SNPs, for example) thus can serve as surrogate “tags” for the disease mutation. Note, however, that as generations pass and individuals become ever more distant relatives (to a point when social/cultural “memory” of genetic relationship is usually lost), different families will produce recombination events at different points near the disease mutation. Therefore, at a population level, unrelated individuals carrying the disease marker will carry variable lengths of DNA on which markers linked to the disease variant ride. Stated another way, unrelated individuals carrying the disease variant will carry *haplotypes* that become more similar to one another as the boundaries of the haplotypes are moved closer to the disease variant. Thus, the closer a marker is to the disease variant, the more likely it is to be originally linked to the variant. When a marker is close enough to a disease marker that the number of recombination events in the population has not yet completely randomized, and the odds are high that it is on the same ancestral stretch of DNA (haplotype) as the disease variant, the marker and the disease variant are correlated and are said to be in *linkage disequilibrium* (LD). Knowing the allele of a marker variant in LD with a disease variant can therefore allow one to predict the allele of the disease variant (i.e., the marker and the disease variant are not statistically independent).

Several factors influence the length of DNA over which LD occurs. The most important are the geographic origins of the population from which an individual is drawn and the history of that population. For example, sub-Saharan African populations are ancient and reflect the greatest proportions of the total human pool of variation, because most of the human species' history predates migration of humans out of Africa. Therefore, on average, sub-Saharan African populations have undergone the greatest number of recombination events since a given pair of unrelated individuals shared a common ancestor. Those individuals thus share only short stretches of ancestral chromosomes (which are said to be *identical by descent*, or IBD). Non-African populations all derive from a relatively small number of migrants who left Africa within approximately the last 100,000 years. Thus, Europeans, Eastern Asians, or Native Americans share longer stretches of DNA IBD within their respective continental groups than do sub-Saharan Africans ([Daly et al. 2001](#); [Gabriel et al. 2002](#); [Patil et al. 2001](#); [Reich et al. 2001](#)). On the other extreme, individuals from reproductively isolated populations, in which a small recent founder population has expanded with little admixture (i.e., introduction of outside individuals into the mating pool), share longer blocks of ancestral chromosomes IBD ([Shifman and Darvasi 2001](#)). An example of such an isolate is the Icelandic population, which derives almost exclusively from a small number of migrants who arrived on the island only several hundred years ago ([Helgason et al. 2003](#)).

Another factor contributing to the complexity of patterns of LD is the fact that recombination events do not occur with the same likelihood across all parts of the genome ([Phillips et al. 2003](#); [Reich et al. 2002](#)). In addition to a

general pattern in which more telomeric regions of chromosomes are more likely to recombine than centromeric regions, specific “hot spots” of recombination have been identified that are spaced unevenly along chromosomes. This variation across the genome in the likelihood of recombination results in the observation that certain stretches in the genome (sometimes referred to as *blocks*) have undergone relatively little recombination over the generations and therefore show strong LD among SNPs in the region. Such regions of high LD can span millions of bases, whereas other regions in the same population have recombined more frequently, resulting in very short blocks of LD (e.g., <5,000 bp). It is important to note that the observed haplotypes formed by the SNPs within a given stretch of chromosome usually represent only a small proportion of all possible haplotypes (for SNPs, the number of possible haplotypes= $2^n$ , where  $n$ =the number of SNPs defining the haplotype). For this reason, such regions of high LD are also called *haplotype blocks* ([Daly et al. 2001](#); [Gabriel et al. 2002](#); [Patil et al. 2001](#); [Reich et al. 2001](#)).

### **Catalogues of human genetic variation.**

Originally, the HapMap (genotyping) and subsequently the 1,000 Genomes (next-generation sequencing) projects provided a high-resolution map of the landscape of human genetic variation. The HapMap project included 1.6 million SNPs from 11 different populations. However, in June 2016, the HapMap project was decommissioned, having been eclipsed by the 1,000 Genomes project. The 1,000 Genomes project aimed to discover the genetic variants with frequencies of at least 1% in the population by mapping 1,000 genomes. The pilot-phase milestone ([1000 Genomes Project Consortium et al. 2010](#)) and the successful

completion of 1,092 genomes in 2012 ([1000 Genomes Project Consortium et al. 2012](#)) continue to be improved (now overseen by the International Genome Sample Resource), with structural variations of 2,504 genomes from 26 populations now mapped ([Auton et al. 2015](#); [Sudmant et al. 2015](#)).

**LD and replication of association studies.** It is now general consensus that finding “true” genetic associations of SNPs in psychiatric disorders demands high-powered studies and replication in independent patient cohorts. As a result of varying founder effects, the verification of a specific SNP might fail in populations with different ancestry, in which case other SNPs in proximity can help to determine the universal significance of that given genetic association.

## Population Stratification

Frequencies of specific alleles can vary to a large degree among different populations. The frequency of the S allele of the 5HTTLPR, for example, is approximately 40%–50% in European, approximately 70%–80% in East Asian, and approximately 25% in African populations ([Gelernter et al. 1999](#)). Spurious associations can thus be found if subjects for a genetic association study are sampled from genetically different subpopulations (with different marker allele frequencies) in different proportions in case and control participants, for example. False-positive associations can also result if an outcome is more prevalent in one subpopulation, perhaps because of different environmental exposure, so that individuals from this subpopulation will be represented more frequently in the case as opposed to the control group. Differences in allele frequencies between

comparison groups can thus result from differences in the population structure of the sample alone, without any causal relationship to the outcome of interest. This problem is called *population stratification* and is exemplified by the hypothetical example of the “chopsticks gene” ([Hamer and Sirota 2000](#)).

Several methods have been developed to address population stratification in genetic association studies. Family-based approaches to genetic association studies, such as the transmission disequilibrium test (TDT; [Spielman et al. 1993](#)) and the haplotype-relative risk (HRR) method ([Knapp et al. 1993](#)), are robust to population stratification. In the TDT, rather than comparing allele frequencies between case and control subjects, genotypes are determined in *probands* (individuals who serve as the starting point for the study) and their parents. To be informative, at least one parent must be heterozygous at the marker of interest (this is one of the disadvantages of the method in its original form: in some cases, not all families can be used). The allele transmitted to the proband from each parent is recorded, as well as the nontransmitted allele. Under the null hypothesis of no linkage or association, the expected chance of each allele’s transmission is 50%. Significant deviations from that chance provide evidence for association (and linkage) between the trait and the marker. The HRR method is similar, except that the frequency of the nontransmitted alleles is compared with that of the transmitted alleles over a large number of families. Each family thus provides its own control, and because the proband is always matched for the population background of the parents, population stratification cannot arise.

Methods based on the TDT have been developed to allow transmission disequilibrium testing in larger family groups. Such family-based association tests offer the advantage of using more of the available genetic information from each family ([Horvath et al. 2001](#)). The major disadvantage of the family-based methods is that it is often impractical to gather families, especially in disorders such as schizophrenia or substance use disorder, which are often associated with familial estrangement, or in age-related disorders such as Alzheimer's disease, in which surviving relatives (especially parents) may not be available. An additional problem with family-based association studies is that they generally have less statistical power than case-control studies ([Risch and Merikangas 1996](#)).

To control for population stratification in case-control studies, several methods have been suggested. One approach is to estimate, and then correct for, the expected degree of stratification by typing a series of unlinked markers across the genome ([Devlin and Roeder 1999](#); [Pritchard et al. 2000](#)). The method of genomic control ([Devlin and Roeder 1999](#)) derives an inflation factor, the so-called  $\lambda$  value, by comparing observed with expected test statistics. This value is then used to rescale association results. One disadvantage of this approach is that  $\lambda$ , and hence inflation, is assumed to be constant across the genome.

Structured association ([Rosenberg et al. 2002](#)) involves the use of a clustering algorithm to assign samples to subpopulations. Association statistics are computed stratified by cluster.

Principal components analysis is another widely used method of detecting and correcting for spurious associations resulting from population stratification ([Price](#)

[et al. 2006](#)). In this approach, the main axes of variation, also called *principal components*, are plotted against each other to identify possible population outliers or clusters. These main (principal) components are also included as covariates in subsequent association analyses to correct for population admixture.

## Genomewide Association Studies

### New Possibilities From the Human Genome Project

Despite more than 40 years of intense research on a series of promising markers, none have thus far been validated as diagnostic tools or predictors of treatment response. In addition, most of the past approaches were hypothesis driven, relying on our limited knowledge of the pathophysiology of psychiatric disorders. With the sequence of the human genome being publicly available since 2001 ([Lander et al. 2001](#); [Venter et al. 2001](#)), a variety of novel research tools are now accessible that may yield unbiased, hypothesis-free insight into the pathophysiological underpinnings of certain psychiatric disorders. These new tools combine knowledge of the sequence of the human genome with miniaturized assays amenable to high-throughput processing or next-generation sequencing methods for a parallel analysis of the whole genome. One can use these tools to investigate the whole genome at the level of the DNA (genomics), all RNA (transcriptomics), and all protein/DNA and protein/RNA interactions (proteomics) in a single experiment. Additionally, similar “omic” approaches are possible at the level of the proteome, including posttranslational modifications. These approaches

have to deal with increasing levels of complexity, because the approximately 20,300 human genes are expected to give rise to at least 10 times as many protein isoforms with a multitude of posttranslational modifications, such as phosphorylation and glycosylation. In addition, the complexity of RNA analysis is massively increased because of differential splicing and noncoding RNAs. These unbiased whole-genome-based approaches can be used to identify novel pathways and molecules involved in the pathogenesis of psychiatric disorders.

In this chapter, we focus primarily on genomewide SNP association studies and their effect on psychiatric genetics. For additional information on the effects of omics on pathophysiological concepts in psychiatry, the reader is referred to the reviews of [Biesecker and Peay 2013](#); [Gratten et al. 2014](#); [Kato 2015](#); and [Schreiber et al. 2013](#).

## Genomewide SNP Arrays

**How many SNPs?** The presence of LD in the human genome allows the investigator to evaluate a large extent of the common genetic variation with selected markers. Estimates of the number of SNPs necessary to account for most of the common sequence variation across the genome (e.g., to account for SNPs with minor allele frequencies of 1% or greater) have varied over time, with estimates ranging from as few as 10,000–100,000 to more than a million SNPs. Thanks to the HapMap, 1,000 Genomes, and ENCyclopedia Of DNA Elements (ENCODE) resequencing projects ([Altshuler et al. 2010](#); [www.hapmap.org](http://www.hapmap.org)), we can efficiently cover the entire genome using SNP assays. Even though the cost for next-generation sequencing has decreased dramatically in the last decade, and the \$1,000

genome was made available in January 2014 by Illumina, array-based methods are still much more cost and time efficient, especially given the enormous sample sizes (10,000 cases and greater) required to identify disease loci in psychiatric traits. These massive genotyping and resequencing projects have confirmed the segments of long LD in the genome and thus the possibility of using tag SNPs (see discussion in “Linkage Disequilibrium” earlier in this chapter) for each of these segments. Using the data from several hundred thousand SNPs should be sufficient to cover most common variants in Caucasians; more SNPs will be necessary in African populations with shorter LD distances (for a review, see [Hirschhorn and Daly 2005](#)).

Certainly to date, genomewide association studies (GWAS) that use arrays have been the most common approach to identifying disease associations across the whole genome. However, next-generation sequencing methods are the most comprehensive, able to interrogate all 3.2 billion bases of the human genome, including rare and private mutations. This unbiased detection of changes at bp resolution makes next-generation sequencing attractive ([Precone et al. 2015](#)). Cost of sequencing depends on both the length of the genome and the depth of sequencing (i.e., the coverage, defined as the number of times a genomic region is read in the sequencing process). Next-generation sequencing typically allows *deeper sequencing* (i.e., at a coverage of  $>10\times$  ).

Reduced cost for more focused approaches can be achieved by preselecting (i.e., targeting) only parts of the genome. The most common targeted next-generation sequencing method is *whole-exome sequencing*. The *exome* makes up less than 2% of the genome but contains many known disease-causing rare variants ([Tennesen et al.](#)

2012). This narrower focus makes whole-exome sequencing a cost-effective targeted method with high coverage. The higher coverage possible with whole-exome sequencing allows identification of rare variants that currently would be too expensive with whole-genome sequencing.

The last few years have yielded a profusion of published studies in which whole-exome sequencing was used, some of which apply to psychiatry; for comprehensive reviews, the reader is referred to [Kato \(2015\)](#) and [Schreiber et al. \(2013\)](#). Some of the most notable findings in psychiatric research from whole-exome sequencing have been in autism spectrum disorder ([Chapman et al. 2015](#); [Toma et al. 2014](#)). It should be noted that in the future, communicating the results of whole-genome sequencing to patients will almost certainly raise ethical questions ([Biesecker and Peay 2013](#)), given that information beyond genetic risk for the interrogated disease will be available.

A major drawback of whole-genome LD-based approaches to association testing, such as those just outlined, is that most sequence variation in the genome is *rare*, with minor allele frequencies too small to be detected with any power by even very dense maps of SNPs. Thus, to the degree that the genetic underpinnings of complex disease deviate from the “common disease, common variant” hypothesis, whole-genome SNP scans will be inadequate to detect associated genes ([Zwick et al. 2000](#)). This concern is not merely theoretical. Thus, it is abundantly clear that in Mendelian diseases, such as cystic fibrosis, in which variation at only one *locus* accounts for the disease, a multitude of very rare *sequence variants* are causal in different families. Rare variation also clearly contributes to complex disease—most notably, autism spectrum disorder ([Levy et al. 2011](#); [Merikangas et al. 2015](#); [Sanders et al. 2011](#)). In all

likelihood, complex disorders will represent a mixture of contributions from rare and common variants, so that methods appropriate for both types of variation will need to be developed and implemented.

**How many individuals?** Genomewide associations require massive correction for multiple testing so that genomewide significant  $P$  values less than  $5 \times 10^{-8}$  can be achieved. These necessarily low alpha levels, together with the expected low odds ratios (ORs) associated with identified susceptibility variants, require large sample sizes for adequate power. When one surveys genomewide association discoveries over time, it can be seen that the larger the sample size, the more genomewide association hits are found (see Figure 2 in [Visscher et al. 2012](http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3257326/figure/figure2); available at: [www.ncbi.nlm.nih.gov/pmc/articles/PMC3257326/figure/figure2](http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3257326/figure/figure2)).

Power (i.e., the probability of obtaining a true positive result) is determined by sample size, allele frequency, effect size, and significance level. For example, to detect the effect of a susceptibility allele that has a frequency of 20% and an OR of 1.3 with a power of at least 80% and an even more liberal alpha level of  $10^{-6}$ , more than 2,500 cases are necessary. If the allele is rarer (e.g., 10% carriers), at least 6,000 cases would be required ([Wang et al. 2005](#)). Considering a quantitative trait and setting the alpha level to  $5 \times 10^{-8}$ , to detect a variant that explains 0.2% of the variance with a power of at least 80%, more than 10,000 individuals would be needed ([Visscher 2008](#)). Often, these high sample sizes can be reached only within consortia that combine samples from many different studies and meta-analyze them together.

## Current Results From Genomewide SNP Association Studies

In a landmark paper, [Risch and Merikangas \(1996\)](#) suggested that the power of GWAS to detect disease genes for complex diseases will be greater than that of family-based studies. This bold suggestion was presented 5 years before the sequence of the human genome was available and SNPs had emerged as potential tools for this type of study. Now, 20 years later, GWAS with hundreds of thousands of SNPs in tens of thousands of affected individuals and control subjects are identifying novel, hypothesis-free candidate genes for complex disorders.

Because of the numerous statistical tests required, a threshold of  $P < 5 \times 10^{-8}$  has been proposed to control for all independent genetic loci in the genome. Associations surpassing this threshold would then be replicated in independent samples ([Ioannidis et al. 2009](#); [Kraft et al. 2009](#)). The standard presentation of data from GWAS is in a Manhattan plot ([Figure 3-3](#)). The chromosomes of the human genome (indicated by the *red* and *blue* portions of the x axis) and the positions on chromosomes are plotted (x axis) against the  $-\log_{10}$  of the statistically significant association identified (y axis). In case-control studies, the association is tested for a difference in genotype or allele distribution between the two groups. A significant threshold line is often drawn at  $P < 5 \times 10^{-8}$  (indicated by the *red horizontal line* in [Figure 3-3](#)). Significant signals are often located in LD with other SNPs that, in consequence, also show strong associations, so that towers of high  $-\log_{10} P$  values rise above the threshold, thus evoking the city skyline that gives the chart its name.

Although the initial years for GWAS in psychiatry were fraught with disappointment, they brought the realization that only very large numbers can yield reliable associations. This realization led to establishment of the international Psychiatric Genomics Consortium (PGC; [www.med.unc.edu/pgc](http://www.med.unc.edu/pgc)) in 2007 that leads the way on GWAS in psychiatry as a result of its very large clinical cohorts (Sullivan 2010). The PGC involves more than 800 scientists worldwide and currently has samples from more than 900,000 individuals.

The largest molecular study ever to focus on schizophrenia, carried out by the PGC, was published in 2014 (Schizophrenia Working Group of the Psychiatric Genomics Consortium 2014). This groundbreaking study analyzed 36,989 case participants and 113,075 control participants and found 108 independent loci that met genomewide significance (see Figure 3-3). Through this effort, the explained variance of schizophrenia by genetic variation has increased from 3% (in GWAS from 2009) to close to 20% (as of 2014). This study has truly changed the view of genetics in psychiatry, cementing its role unquestionably in the etiology of schizophrenia at least (Flint and Munafò 2014a, 2014b; Need and Goldstein 2014). From the 108 loci identified, the authors estimated more than 600 genes to be involved. Notably, they highlighted the region encoding the extended major histocompatibility complex (MHC). The MHC had already been identified in several previous studies (Purcell et al. 2009) as playing an important role in schizophrenia. Perhaps unsurprisingly, the locus corresponding to the

*DRD2* gene also has been implicated. This gene encodes the D<sub>2</sub> dopamine receptor, a target of many antipsychotic medications. Other interesting genes implicated in the 108 loci include calcium channel subunits and proteins involved in synaptic plasticity. These findings tie in well ([Hall et al. 2015](#)) with the findings of another recent GWAS that implicated calcium signaling ([Ripke et al. 2013a](#)) as well as with the findings of studies on de novo mutations in schizophrenia, which also identified synaptic networks ([Fromer et al. 2014](#)), voltage-gated calcium ion channels, and the signaling complex formed by the activity-regulated cytoskeleton-associated scaffold protein of the postsynaptic density ([Purcell et al. 2014](#)).

Although it has been established that genetics plays an important role in the development of depression (twin studies estimate a heritability of 0.4-0.5), no GWAS to date have been able to conclusively find a consistent genetic association ([Dunn et al. 2015](#)). It has been suggested that the reasons for this limited success are either the highly heterogeneous nature of depression or the failure to take the environmental contributions into account. The PGC has a working group for depression, and in 2013 they published a “mega-analysis” of GWAS for depression ([Ripke et al. 2013b](#)). The authors stated that although this study was the largest case-control GWAS of depression ever to be carried out (with 9,240 case participants and 9,519 control participants), it nonetheless had insufficient power to detect effects seen in complex disorders, so no SNP reached genomewide significance. The PGC now has GWAS data on more than 60,000 individuals.

The CHARGE (Cohorts for Heart and Aging Research in Genomic Epidemiology) Consortium carried out a GWAS meta-analysis with a discovery sample of 34,549 ([Hek et al.](#)

2013). In this study, the investigators examined current depressive symptoms as opposed to lifetime diagnosis of depression. Again, no SNP reached genomewide significance. The authors estimated that a sample of more than 50,000 subjects would be necessary to gain sufficient power. Indeed, when the discovery sample was combined with the replication sample ( $N=51,258$ ), one SNP reached genomewide significance. This association was band 5q21.

The CONVERGE (China, Oxford, and Virginia Commonwealth University Experimental Research on Genetic Epidemiology) Consortium aimed to address the issue of heterogeneity by using a large, homogeneous cohort of patients (CONVERGE Consortium 2015). In 2015, the consortium reported two loci that reached genomewide significance: *SIRT1* and *LHPP*. The cohort consisted of 5,303 Han Chinese women with recurrent depression. When the investigators restricted cases to those with the more severe subtype, melancholia, the *SIRT1* association became even stronger (CONVERGE Consortium 2015).

Whole-genome SNP association studies have been more successful in bipolar disorder, and polymorphisms in the genes encoding ankyrin G (*ANK3*) and the alpha 1C subunit of the L-type voltage-gated calcium channel (*CACNA1C*) have emerged as new candidates for this disorder from data combining several large samples (Ferreira et al. 2008; Kloiber et al. 2012; Schulze et al. 2008). The *CACNA1* gene family also may be of relevance in schizophrenia (Moskvina et al. 2009). Interestingly, the independent samples (Baum et al. 2008a, 2008b; Craddock et al. 2010; Sklar et al. 2008; Wellcome Trust Case Control Consortium 2007) mostly yielded no genomewide significant associations or could not be replicated in single association studies, showing the importance of large sample sizes for these studies.

The ever-growing sets of GWAS data in psychiatric genetics are providing new insights into the genetics of psychiatric disorders. Although promising, these data raise several important issues:

- *Multiple genes of small effects contribute to psychiatric disease.* To identify these effects with sufficient power, large sample sizes of around 25,000 cases will be required, and international collaborations are essential.
- *Genetic susceptibility in psychiatry represents a mixture of contributions from common and rare variants, with rare variants likely predominating in autism spectrum disorder and schizophrenia* ([Lencz et al. 2007](#); [Sutcliffe et al. 2005](#)). Linkage and association studies will need to be combined with resequencing studies to identify these rare variants.
- *Structural variations (CNVs, insertion/deletions, and balanced translocations) in psychiatric genetics are important.* In schizophrenia and autism spectrum disorder, investigation of structural variation has been demonstrated to be a very powerful tool for dissecting the genetics of these disorders ([Cook and Scherer 2008](#); [Marshall et al. 2008](#); [Sebat et al. 2007](#); [St Clair 2009](#); [Szatmari et al. 2007](#); [Weiss et al. 2008](#)). Studies of structural variation have yet to be done for PTSD; for depression and anxiety, the results have been inconclusive or unreplicable (for a recent, thorough review, see [Smoller 2016](#)).

## Use of GWAS Data

Very large sample sizes (of more than 25,000 case participants) are required to adequately power GWAS for complex traits, and the genetic associations point to

multiple variants with small effect sizes. Several tools have been developed to help elucidate the polygenic aspects of disease risk. Two important tools are *pathway/gene set analysis* and *polygenic risk scores*.

**Pathway analysis of GWAS data.** Data generated by a GWAS can be mapped to known biological pathways using *pathway analysis* (also called *gene set enrichment analysis*), thereby providing an enriched set of genes. This analysis can increase the power of the data because association signals are grouped by functionally related genes. Pathway analysis can provide insight into the cell or molecular level pathways underlying the disorder. Pathway analysis has implicated voltage-gated ion channels ([Psychiatric GWAS Consortium Bipolar Disorder Working Group 2011](#)) and hormone action ([Holmans et al. 2009](#)) in bipolar GWAS data sets and neuronal cell adhesion in schizophrenia and bipolar GWAS data sets ([O'Dushlaine et al. 2011](#)). A recent study looked for common biological pathways across schizophrenia, depression, and bipolar disorder from PGC GWAS data ([Network and Pathway Analysis Subgroup of Psychiatric Genomics Consortium 2015](#)). Histone methylation showed the strongest association, but evidence for associations with immune and neuronal signaling pathways and postsynaptic density was also found.

**Polygenic analysis of GWAS data.** Over the past decade, there have been many attempts to identify genes associated with psychiatric disorders using SNP markers. Although GWAS have successfully identified some variants, it is becoming clear that in complex disorders, genetic risk is determined both by many common variants of small effect

and by rare and de novo variants of large effect. This dilemma again illustrates the inadequacy of the “common disease, common variant” model and the limitations of GWAS. As a result, it has been proposed that between these two extremes, there is a middle ground in which moderately penetrant but somewhat rarer variants are being missed (Maher 2008). These missing variants might be unearthed if a single *polygenic risk score (PGRS)* could be calculated. *Polygenic analysis* examines the extent to which heritability is due to the additive effects of many common loci variants that individually are of little effect (Dudbridge 2013). By using all SNPs to examine the net effect on disease risk, a composite score can be calculated, thus providing significant predictive ability. The PGRS is composed of many true but subthreshold variants that GWAS initially might have missed as a result of being underpowered to detect them at the conventional alpha level of  $P=5\times 10^{-8}$  (Gratten et al. 2014). PGRSs can be calculated with bioinformatics software such as PRSice (<http://prsice.info>). Polygenic risk profiling from GWAS can predict case-control status in independent samples. Recent research has suggested that adjustment for LD can improve the predictive performance of PGRSs (Vilhjálmsson et al. 2015).

This new polygenic analysis approach addresses the genetic complexity of psychiatric disorders because their underlying *genetic architecture* is highly polygenic. In the context of a particular disease, the term *genetic architecture* refers to “the number, frequency, and effect sizes of genetic risk alleles and the way in which they combine together” (Wray and Visscher 2010, p. 14). The PGRS also can be analyzed in relation to the clinical

phenotype and against quantitative traits related to the disorder.

The recent polygenic analysis study in schizophrenia ([Schizophrenia Working Group of the Psychiatric Genomics Consortium 2014](#)) validated the polygenic analysis approach. PGRSs can predict schizophrenia case-control status, albeit with varying sensitivity and specificity, possibly because of differing sampling strategies ([Meier et al. 2016](#)). In contrast to twin and family studies, the polygenic heritability approach provides information on the frequency of the alleles underlying the phenotype.

By supplementing PGRSs with family history, risk prediction can be significantly improved. This strategy has yet to be used in the field of psychiatry but has been successful in improving the predictive performance of PGRSs in other disorders ([Chatterjee et al. 2013](#)).

In schizophrenia at least, PGRSs may improve future clinical decision making and may even inform prevention strategies. Evaluation of the clinical efficacy of a PGRS can be carried out via the receiver operating characteristic curve. The area under this curve expresses the accuracy with which high- and low-risk groups can be distinguished ([Janssens et al. 2007](#)). PGRSs may be able to personalize genomics in psychiatry in the future ([Smoller 2014](#)).

## Cross-Disorder Studies

The traditional view that psychiatric disorders are distinct in nature is being challenged by evidence emerging from studies looking at the genetic landscape ([Cross-Disorder Group of the Psychiatric Genomics Consortium 2013](#)). Some disorders clearly share genetic risks. The genetic

architecture correlation calculated with common SNPs was  $r=0.68$  for bipolar disorder and schizophrenia,  $r=0.47$  for bipolar disorder and depression, and  $r=0.43$  for schizophrenia and depression ([Cross-Disorder Group of the Psychiatric Genomics Consortium 2013](#)).

An attempt has been made to identify the underlying molecular source of the cross-disorder overlap. The [Cross-Disorder Group of the Psychiatric Genomics Consortium \(2013\)](#) examined the five PGC disorders: schizophrenia, depression, bipolar disorder, autism spectrum disorder, and ADHD (S.H. [Lee et al. 2013](#)). They looked for SNPs in a GWAS of samples from 33,332 case participants and 27,888 control participants. Findings from these cross-disorder studies seem to confirm the biological overlap of psychiatric traits. Four SNPs with genomewide significance on cross-disorder risk were found: *AS3MT*, *ITIH3*, and the L-type voltage-gated calcium channel subunits *CACNB2* and *CACNA1C*. These findings again implicate calcium channels in psychopathology.

## Gene × Environment Interaction Studies

To date, most genetic association studies have searched for main associations between sequence variants and psychiatric disorders. This approach ignores the clear reality that environmental factors contribute importantly to psychiatric illness. For example, it is clear that childhood traumatic experiences substantially increase the risk of stress-related disorders ([Heim et al. 2010](#)). Since the landmark paper of [Caspi and Moffitt \(2006\)](#), there has been increasing interest in G×E interactions in the field of

psychiatry. [Caspi et al. \(2003\)](#) showed that the 5HTTLPR genotype interacts with exposure to early trauma to increase the risk of depression differentially in carriers of the S allele.

Although most G×E interaction studies focus on detrimental effects of the environment, the genetic moderation of positive and protective environmental factors should not be ignored ([Kim-Cohen and Turkewitz 2012](#)). Examining the effect of negative versus positive as well as shared versus individual environmental factors against genetic variation will help to explain individual differences in risk or resilience ([Klengel and Binder 2013, 2015](#)). However, careful interpretation of G×E studies is required, because they can be fraught with methodological problems ([Duncan and Keller 2011](#); [Munafò et al. 2009](#)).

From a theoretical perspective, searching for such G×E interactions makes sense. Thus, any statistical interaction is bound at the upper end of its effect size by the magnitude of the main effects being considered. When environmental factors such as early trauma, which have large effect sizes, are examined together with genetic factors, which are expected generally to have small effect sizes, the result can be greater power to detect G×E interactions than to detect the main effects of the gene. Thus, an argument can be made (which by no means is accepted by all) that future genetic studies of psychiatric disorders and other complex disorders should be based on models that incorporate both genetic and environmental factors. Indeed, the modification of PGRSs by environmental effects is one way forward in translational research in psychiatry ([Duncan and Keller 2011](#); [Sharma et al. 2016](#)).

Unfortunately, most G×E studies conducted to date have been inadequately powered to detect a strong effect

([Duncan et al. 2014](#)); however, with the availability of established risk loci from GWAS, the field should open up to study a new range of G×E effects.

One notable, confirmed G×E interaction is that of genetic variants in *FKBP5* with childhood abuse, contributing to the risk of several psychiatric disorders in the presence of childhood trauma ([Zannas et al. 2016](#)). This interaction influences the epigenetic response to childhood trauma as well as neural circuit activation in response to stress and threat ([Klengel and Binder 2015](#); [Klengel et al. 2013](#)). Other confirmed G×E interactions include that between an SNP in the *AKT1* gene and cannabis use in the development of psychosis ([Di Forti et al. 2012](#)), that between an SNP in the serotonin transporter gene and childhood maltreatment in the development of depression ([Karg et al. 2011](#)), and that between the *BDNF* gene and stressful life events in the development of bipolar disorder.

The ENCODE project has laid to rest the postgenomic idea that non-protein-coding DNA is “junk DNA” by successfully assigning biological functions to 80% of the genome and discovering that 95% of the genome is within 8 kilobases of a protein–gene interaction. It is hoped that the ENCODE project ([Kavanagh et al. 2013](#)) will continue to provide new insights into G×E interactions as it annotates regulatory regions that are inherently relevant to the genomic response to environmental cues.

## Conclusion

---

Taken together, epidemiological, cytogenetic, linkage, and association studies in psychiatric genetics to date paint a

picture of highly complex genetic influences on psychiatric disorders. As [Kendler \(2005\)](#) pointed out more than a decade ago, the phrase “a gene for...” will *not* apply to psychiatric genetics. As [Kendler \(2005, p. 1243\)](#) went on to note: “the impact of individual genes on risk for psychiatric illness is small, often nonspecific, and embedded in a complex causal pathway.” We suggest that the field adopt strategies that are tailored to the most likely disease models. Three main strategies for addressing this issue are proposed.

First, we may need to reconsider how we define cases or the phenotype of interest. Our current classification schemes are not likely directly reflective of the underlying biology—and thus the genetic determinants—of psychiatric disease. The currently used diagnostic algorithms (DSM-5 [[American Psychiatric Association 2013](#)] and ICD-10 [[World Health Organization 1992](#)]) group diagnoses by symptoms and clinical course, which may not reflect a common biology but rather a final common pathway of several different pathophysiological disturbances. That recognition has led some to propose the use of intermediate phenotypes, including neurophysiological, biochemical, cognitive, and endocrine measures ([Gottesman and Gould 2003](#); [Hasler et al. 2004](#); [Insel 2014](#)), in psychiatric genetic studies in order to create biologically more homogeneous subgroups of patients and thus to increase the power to detect case-control associations. Another important consideration is that some symptoms are common to several different diagnoses, and the genetic susceptibility to develop these symptoms may be common across disorders ([Doherty and Owen 2014](#)). In fact, evidence indicates that the major psychiatric disorders may share susceptibility genes ([Cross-](#)

Disorder Group of the Psychiatric Genomics Consortium 2013).

Second, environmental measures should be included more consistently in genetic studies, including whole-genome association studies. Epidemiological (Kendler 1995) as well as molecular genetic studies have now repeatedly shown the importance of G×E interactions in psychiatric disease (Klengel and Binder 2015). Genetic effects may be obscured by unmeasured environmental effects, so that different environmental exposures in replication samples may be one source of nonreplication of genetic association.

Third, one should not forget that SNPs are simply the most common and convenient type of genetic variant, not the only type. Other types of variation, such as CNVs, are equally important (Zarrei et al. 2015; Sebat et al. 2004).

Thanks to ever-advancing technologies, genetics and genomics are entering a new and exciting era. Progress will no doubt advance rapidly, bringing with it the potential to redefine psychiatry.

The associations between hormonal changes and psychiatric disorders have long been recognized, but only in recent decades have the underlying mechanisms begun to be understood. A renewed interest in the associations linking stressful early life events, hypothalamic-pituitary-adrenal (HPA) axis dysregulation, inflammatory processes, and potential vulnerability to depression, psychosis, and posttraumatic stress disorder (PTSD) has prompted a resurgence of research in this field. Although the association between reproductive hormone changes and psychiatric disorders has been less well studied, there is likewise a growing clinical recognition of the burden of postpartum psychopathology and a new impetus for

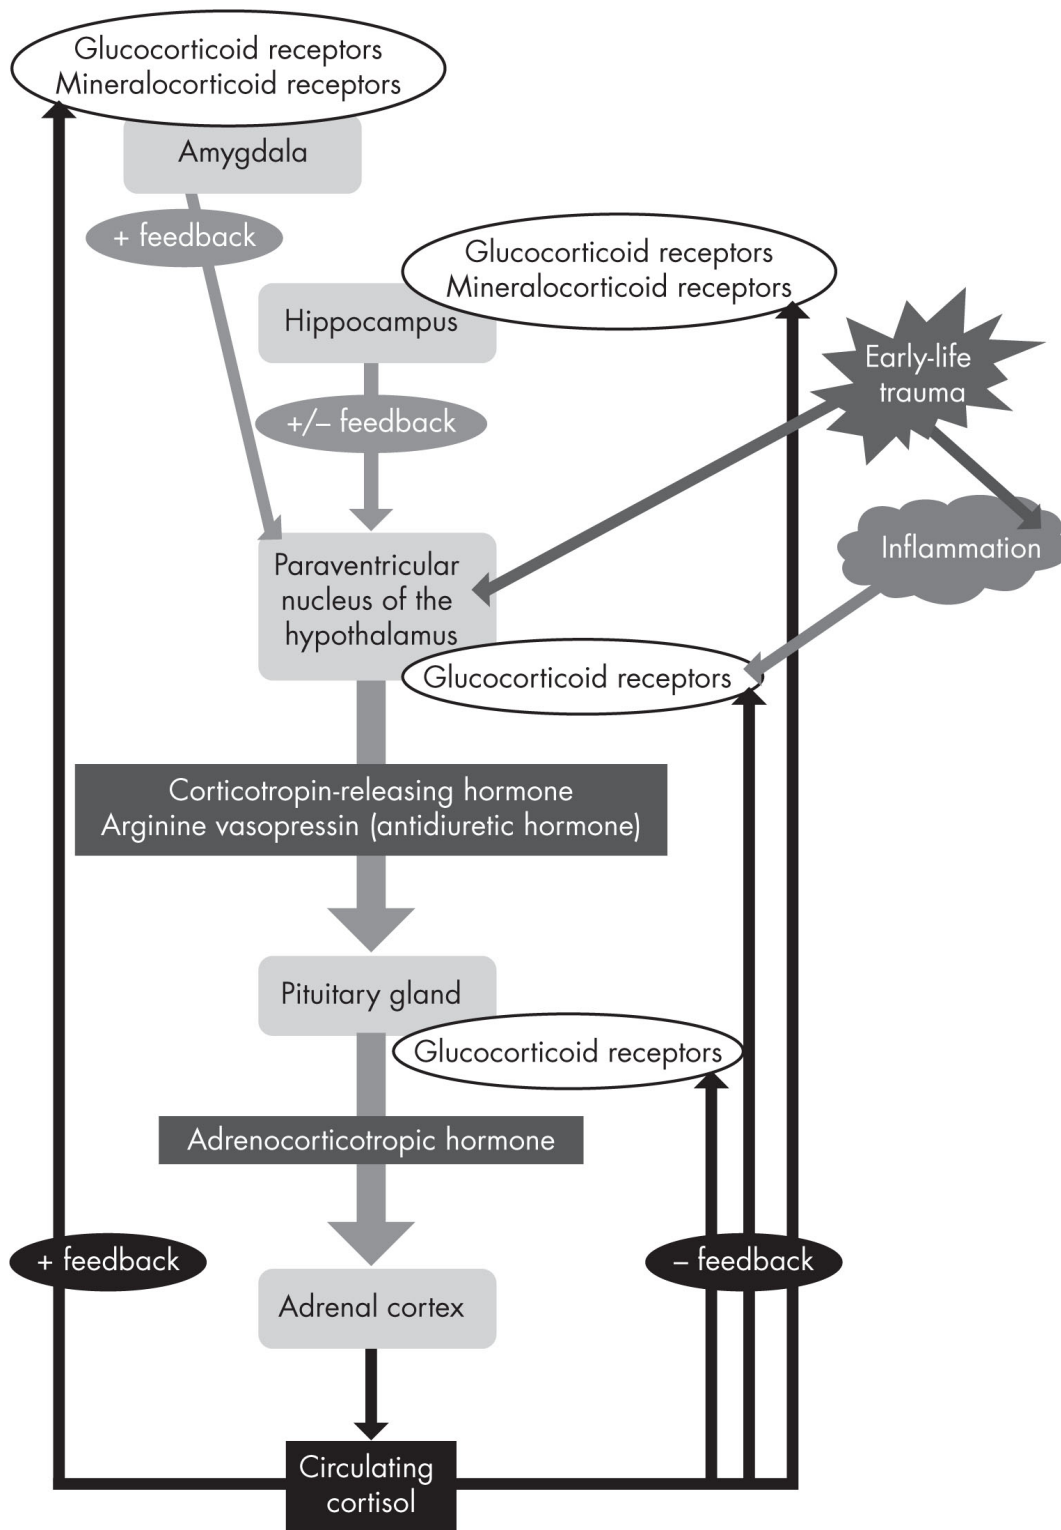

research progress in this area. A full account of how each endocrine system influences neurobehavioral function is beyond the scope of a single chapter; we focus here on summarizing the most firmly established findings from classic literature in the field, and on providing an overview of some recent promising research findings.

## Hypothalamic-Pituitary-Adrenal Axis

---

The HPA axis produces a primary response to stressors to ensure adaptation to environmental change and to maintain homeostasis ([Figure 4-1](#)). In response to a threat, which may be physical (such as starvation) or psychological (such as perceived danger or a stressful life event), an increase in synthesis of corticotropin-releasing hormone (CRH) occurs in the hypothalamus. CRH stimulates secretion of pituitary adrenocorticotrophic hormone (ACTH), which in turn triggers production of glucocorticoids by the adrenal cortex in a feedforward cascade. Cortisol is the main glucocorticoid, and its secretion is tightly controlled by the negative-feedback effects of glucocorticoids at both pituitary and brain sites, such as the hippocampus and hypothalamus ([Pariente and Lightman 2008](#)). These effects include rapid inhibition of the stress response, preventing oversecretion of glucocorticoids ([Keller-Wood and Dallman 1984](#)) via regulation of messenger ribonucleic acid (mRNA) and subsequent protein stores of the ACTH precursor pro-opiomelanocortin ([Roberts et al. 1979](#)) and CRH in the central nucleus of the amygdala ([Makino et al. 1994](#)).

**FIGURE 4-1.** Schematic diagram of the hypothalamic-pituitary-adrenal (HPA) axis.

***See [Plate 14](#) to view this figure in color.***

In response to a threat, the hypothalamus synthesizes corticotropin-releasing hormone (CRH), which stimulates pituitary secretion of adrenocorticotrophic hormone (ACTH), triggering adrenal glucocorticoid production in a feedforward cascade.

The HPA axis regulates peripheral body functions, including metabolism and immune response, as well as brain function. For example, glucocorticoids have well-established effects on carbohydrate metabolism, modulating pancreatic insulin release and hepatic and nonhepatic responses to insulin. Glucocorticoids have a wide range of enhancing and suppressive actions on both innate and adaptive immune responses, including upregulation of phagocytosis by neutrophils and macrophages; suppression of cytokine release by type 1 T helper (Th1) cells; and selective enhancement of type 2 T helper (Th2) cells ([Franchimont 2004](#)). Centrally, glucocorticoids regulate neuronal survival, neurogenesis, the acquisition of new memories, and the emotional appraisal of events, as well as the sizes of complex anatomical structures such as the hippocampus ([Herbert et al. 2006](#)).

Stressful stimuli activate all levels of the HPA axis, causing increases in CRH, ACTH, and cortisol secretion. However, these increases are superimposed on an intrinsic circadian pattern of HPA activity driven by the suprachiasmatic nucleus. HPA axis hormone secretion is pulsatile in nature, with the trough of integrated secretion occurring in the evening and early nighttime and the peak of secretion occurring just before awakening; active secretion continues throughout the morning and early afternoon. Under normal conditions, the pulsatile secretion of glucocorticoids causes

continuous mineralocorticoid receptor (MR) activation and phasic and short-acting glucocorticoid receptor (GR) activation after each endogenous pulse ([Conway-Campbell et al. 2007](#)). The synergy of MR and GR activation is key to mediating glucocorticoid feedback inhibition. The pulsatile or “ultradian” pattern of HPA axis hormone secretion is essential for optimal transcription as well as for maintenance of neuroendocrine and behavioral responsiveness to stress. Recent research suggests that chronic (e.g., obstructive sleep apnea) and acute disease states (e.g., cardiac surgery) are associated with disruptions of the dynamic changes in adrenocortical steroid-producing cells that are required to maintain the normal ultradian pattern ([Spiga and Lightman 2015](#)).

## The HPA Axis in Depression, Psychosis, and Posttraumatic Stress Disorder

### **Depression**

Major depressive disorder (MDD) is widely considered to represent a maladaptive, exaggerated response to stress, and although it is associated with abnormalities in multiple endocrine systems, the HPA axis seems to be the most significant of these systems, with overactivity being a well-established phenomenon in depression. Studies have demonstrated cortisol hypersecretion in a proportion of people with depression, as evidenced by elevated 24-hour urinary free cortisol (UFC) and plasma and cerebrospinal

fluid (CSF) cortisol concentrations ([Carroll et al. 1976](#); [Rubinow et al. 1984](#)).

The role of hypothalamic CRH secretion in triggering the HPA axis response led to the CRH hypothesis of depression ([Nemeroff 1996](#)), which proposed that HPA hyperactivity in depression is attributable to CRH overexpression. This hypothesis is supported by evidence of elevated CRH levels in the lumbar CSF of depressed patients compared with nondepressed controls ([Banki et al. 1992](#)) as well as postmortem evidence of elevated CRH levels in the cisternal CSF of people who died by suicide ([Arató et al. 1989](#)). The presence of elevated CSF CRH further suggests hypersecretion of CRH by sources outside the hypothalamus, such as the amygdala, which is noted to be overactive in depression ([Drevets 2003](#)). Studies in rodents have found that HPA axis hyperactivity can be stimulated by chronic overexpression of CRH by the central amygdala ([Flandreau et al. 2012](#)).

In addition, HPA axis hyperactivity is thought to result from impaired negative feedback, mediated by changes in the binding of endogenous glucocorticoids to MR and GR (see [Figure 4-1](#)). The MR has a high affinity for endogenous corticosteroids, whereas the GR has a high affinity for dexamethasone and a lower affinity for endogenous corticosteroids. This profile supports a potentially more important role for the GR in regulating responses to stress in disorders associated with high levels of endogenous glucocorticoids, such as depression. Indeed, impaired GR-mediated negative feedback by glucocorticoids in MDD is suggested by studies reporting nonsuppression of cortisol secretion on the dexamethasone suppression test and other studies demonstrating a lack of ACTH inhibition in response to CRH following dexamethasone pretreatment (i.e., the

combined dexamethasone/CRH test) ([Pariante and Lightman 2008](#)).

This hypothesis is supported by evidence that impaired HPA axis feedback inhibition by glucocorticoids resolves after successful antidepressant treatment. Furthermore, persistently impaired HPA axis negative feedback is associated with a high risk of early relapse and poor outcomes following discharge ([Zobel et al. 2001](#)). This inhibition of GR-mediated negative feedback could be due to reduced expression of the GR, as evidenced by both postmortem studies of human brains ([Webster and Carlstedt-Duke 2002](#)) and studies of the peripheral blood of depressed patients ([Cattaneo et al. 2013](#); [Nikkheslat et al. 2015](#)). Experimental models of GR resistance have shown that activation of the P38 mitogen-activated protein kinase pathway by proinflammatory cytokines can reduce GR function ([Miller and Raison 2006](#)), a result that yields a potential explanation for the association of depression with inflammation, HPA axis hyperactivity, and glucocorticoid resistance.

In addition to considerable evidence supporting the role played by the GR in HPA axis regulation, there has been increasing interest in the effects of the MR, which is found at high concentrations in limbic brain regions and has a high affinity for cortisol and corticosterone in rats. Dexamethasone binds only to GR, meaning that both the dexamethasone suppression test and the combined dexamethasone/CRH test assess only GR function. Spironolactone (the precursor of the MR antagonist canrenoate) activates the HPA axis through blockade of MR-mediated negative feedback by endogenous glucocorticoids. A 2003 study found elevated cortisol secretion in response to spironolactone challenge in

depressed patients compared with nondepressed controls ([Young et al. 2003](#)), suggesting increased MR activity in depression, whereas a more recent study found the opposite, perhaps because patients were treated with antidepressants and benzodiazepines ([Juruena et al. 2009](#)). Prednisolone is a synthetic glucocorticoid that, unlike dexamethasone, binds to the GR and the MR with similar affinity. [Juruena et al. \(2009\)](#) found normal cortisol secretion in response to administration of prednisolone (which affects both GR and MR) in depressed patients but impaired cortisol secretion in response to dexamethasone (which affects GR only). It is notable that nonsuppression in response to prednisolone (but not to dexamethasone) predicted lack of treatment response to antidepressants ([Juruena et al. 2009](#)).

Some studies suggest that HPA axis hyperactivity does not occur uniformly in all patients with depression at all times. For example, [Posener et al. \(2000\)](#) demonstrated different patterns of HPA axis abnormality in patients with psychotic and nonpsychotic depression. In this study, patients with nonpsychotic depression showed significantly lower 24-hour cortisol levels compared with controls but no difference in ACTH levels, whereas patients with psychotic depression showed significantly higher 24-hour mean ACTH levels compared with controls but no difference in cortisol levels ([Posener et al. 2000](#)).

The evidence described here highlights the role of the adrenal gland in HPA axis hyperactivity in depression. The process-oriented model proposed by [Parker et al. \(2003\)](#) postulated that in acute depression, excess cortisol results from hypersecretion of both hypothalamic CRH and pituitary ACTH, whereas in chronic depression, elevated cortisol levels are maintained by increased adrenal

sensitivity to ACTH and negative feedback by glucocorticoids despite lower ACTH levels ([Parker et al. 2003](#)). Quantification of hormone-level variability through use of the approximate entropy statistic (ApEN) yielded significantly increased cortisol ApEN and significantly reduced ACTH ApEN in men with MDD compared with control participants ([Posener et al. 2004](#)), a finding that suggests abnormal cortisol regulation and highlights the role of adrenal gland pathology in depression. This finding is in keeping with findings of previous studies demonstrating adrenocortical hypertrophy in people with depression compared with healthy controls ([Nemeroff et al. 1992](#)) as well as resolution of the hypertrophy following effective antidepressant treatment ([Rubin et al. 1995](#)). A recent study that used magnetic resonance imaging to investigate the association of depression with cardiovascular disease found elevations in adrenal gland volumes that correlated with increased intra-abdominal and pericardial volumes of adipose tissue ([Kahl et al. 2015](#)).

Of note, studies investigating early stressful life events suggest that HPA axis hyperactivity may be a premorbid risk factor for depression rather than a consequence or an epiphenomenon of depression. Neonatal rodents and nonhuman primates separated from their mothers for extended periods show HPA axis hyperactivity and CRH-containing circuit overactivation that persist into adulthood ([Sánchez et al. 2001](#)). In humans, marked HPA axis hyperactivity in adulthood has been demonstrated in women with a history of childhood physical and sexual abuse. In a study using laboratory tests of standardized psychosocial stress (e.g., the Trier Social Stress Test), participants with a history of childhood abuse exhibited elevated ACTH secretion and elevated heart rates

compared with participants without such a history, with the most elevated responses and markedly high cortisol levels observed in participants with a history of childhood abuse who were currently depressed ([Heim and Nemeroff 2002](#)). Another study, using the dexamethasone/CRH test, reported persistent HPA axis overactivation in men with a history of early life trauma ([Heim et al. 2008](#)). These findings suggest that the association between HPA axis hyperactivity and depression may indicate a persistent neurobiological predisposition to depression associated with early life stressors. Inconsistencies in the literature regarding HPA axis hyperactivity in depression may be explained by failure to control for exposure to childhood stressful life events. However, although these findings could explain the comorbidity between early life stressors and adult depression, they do not imply inevitability or irreversibility. Indeed, a key finding of mood disorder research has been that polymorphisms in stress-related genes can modify susceptibility to depression after stressful life events. Modification of susceptibility to depression has been shown for the genes encoding the 5-HT transporter ([Caspi et al. 2003](#)), CRH ([Bradley et al. 2008](#)), and the GR-bound protein FKBP5 ([Zannas et al. 2016](#)).

Complementary studies from immunology have demonstrated clinically significant inflammation in adulthood in healthy participants with a history of early life trauma, as evidenced by elevated levels of C-reactive protein (CRP; a peripheral inflammatory marker and an acute phase protein) and interleukin (IL) 6 during the Trier Social Stress Test ([Danese et al. 2007](#); [Pace et al. 2006](#)). Elevated levels of IL-6, IL-1 $\beta$ , tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), and CRP have also been reported in patients with depression ([Raison et al. 2006](#)). Similarly to HPA axis

feedback impairment, CRP elevation normalizes following antidepressant treatment ([O'Brien et al. 2006](#)). One unifying hypothesis to explain these findings is that in patients with depression or a history of childhood trauma, glucocorticoid resistance (ineffective action of glucocorticoid hormones on target tissues, as seen in HPA axis hyperactivity) triggers immune activation ([Danese et al. 2008](#)).

## Psychosis

HPA axis abnormalities likewise have been demonstrated in patients with psychosis. Studying patients who are experiencing their first psychotic episode has been considered the preferred approach to avoid confounding by illness and treatment duration. A recent systematic review ([Borges et al. 2013](#)) reported evidence of HPA axis hyperactivity in first-episode psychosis, with higher baseline cortisol levels and blunted cortisol awakening responses in patients compared with control participants. Studies of patients at ultrahigh risk of developing psychosis have reported associations between higher cortisol levels and prodromal and psychotic symptoms ([Corcoran et al. 2012](#); [Mittal and Walker 2011](#)), and pituitary gland enlargement at baseline has been shown to predict future psychotic illness ([Garner et al. 2005](#)). The association of HPA axis abnormalities with psychosis-like symptoms has also been found in patients with schizotypal personality disorder ([Mittal et al. 2007](#)) and in healthy participants scoring high on measures of schizotypal traits ([Hori et al. 2011](#)). Elevated ACTH responses to stress ([Brunelin et al. 2008](#)) and raised cortisol at baseline and following stress ([Collip et al. 2011](#)) have been demonstrated in healthy relatives of patients with psychosis. Pituitary gland enlargement also

has been reported in first-degree relatives of people with schizophrenia compared with healthy controls ([Mondelli et al. 2008](#)). [Borges et al. \(2013\)](#) suggested that these studies point to the presence of a familial, potentially genetic, vulnerability to HPA axis hyperactivity in individuals who develop schizophrenia. It is noteworthy that studies in two independent samples have identified enlarged pituitary gland volumes—one study in the context of psychotic depression, psychotic mania, and schizophrenia ([Pariante et al. 2004](#)) and the other study in the context of the pre-psychosis prodromal phase ([Garner et al. 2005](#)). A possible mechanism for the pituitary gland enlargement seen in these studies may be ineffective negative feedback by circulating glucocorticoid hormones, leading to proliferation and expansion of the pituitary cells that produce ACTH.

## **Posttraumatic Stress Disorder**

Although there is evidence that HPA axis abnormalities are present in PTSD, methodological difficulties initially made some of the literature challenging to interpret, with evidence of both increased and decreased HPA axis activity based on comorbidity with depression, type of trauma, and other sociodemographic features of the sample. For example, in a study of combat veterans with a diagnosis of PTSD, both low cortisol and enhanced cortisol suppression in response to dexamethasone were reported, irrespective of comorbid MDD ([Yehuda 2002](#)). However, that sample included only male combat veterans, whereas in community samples, women are more likely to experience PTSD ([Frans et al. 2005](#); [Kessler et al. 1995](#)). Furthermore, studies of PTSD in veteran populations are subject to significant confounding with current and past alcohol and substance

use disorders. Additional evidence of elevated CSF CRH levels and blunted ACTH responses to CRH suggests that pituitary CRH receptors are downregulated in PTSD ([Bremner et al. 1997](#)). A study using serial CSF sampling over a period of 6 hours demonstrated elevated CRH despite normal free urinary cortisol in war veterans diagnosed with PTSD compared with veterans without PTSD and healthy controls ([Baker et al. 1999](#)). PTSD studies generally report comorbid depression in participants, and depression studies often fail to measure and report trauma histories. As a result, documented depression confounds much of literature on the HPA axis in PTSD, and undocumented trauma and abuse may confound some of the literature on the HPA axis in depression.

These problems were avoided by [Heim et al. \(2001\)](#) in their studies on childhood abuse and MDD, which examined multiple HPA axis challenges in the same participants. The authors found an effect of early abuse (with comorbid PTSD in 11 of 13 participants) and MDD on stress reactivity, documenting both increased ACTH and increased cortisol response to the stressor in depressed patients with a history of childhood abuse compared with either healthy controls or depressed patients without a history of childhood abuse. In this same cohort, patients with MDD showed a blunted response to CRH challenge irrespective of the presence or absence of an abuse history, whereas patients with a history of childhood abuse who were not depressed showed a heightened response to CRH challenge. Thus, childhood abuse produced an increased pituitary response with adaptive adrenal compensation, a change compatible with low or normal basal cortisol levels. Furthermore, lower cortisol levels and greater CRH suppression in the low-dose dexamethasone suppression

test were found in women with a history of abuse who developed depression but not in those without depression ([Newport et al. 2004](#)), irrespective of PTSD features.

A meta-analysis of 37 studies of basal cortisol levels in adults with current PTSD compared with adults without psychiatric disorders ([Meewisse et al. 2007](#)) examined data from 828 patients and 800 control participants. Although the authors found no significant differences in basal cortisol between the two groups, significantly lower serum cortisol was observed in studies that included only female participants, in studies that investigated physical or sexual abuse, and in studies that used afternoon cortisol sampling. A second meta-analysis of 47 studies comparing patients with PTSD, patients with PTSD and comorbid MDD, and control subjects with and without trauma exposure ([Morris et al. 2012](#)) found that cortisol levels were lower for the PTSD and the PTSD + MDD groups than for the no-trauma control group (which did not differ significantly from the trauma-exposed control group). Cortisol levels in response to dexamethasone suppression testing were lower in the PTSD group, the PTSD + MDD group, and the trauma-exposed control group relative to the no-trauma control group, with effect sizes moderated by age, time since traumatic event, and age at traumatic experience. The authors proposed that whereas lower daily cortisol may represent a marker of PTSD, increased HPA axis response to dexamethasone suppression testing may represent a marker of trauma exposure more generally.

Studies demonstrating increased GR binding and function in patients with PTSD have given rise to the suggestion that hypocortisolism may result from hypersensitivity of negative feedback inhibition ([Yehuda 2006](#)). Indeed, prospective studies have found evidence that the presence of

hypocortisolism prior to traumatic experiences may predict vulnerability to PTSD ([Yehuda et al. 1998](#)), prompting the hypothesis that low baseline cortisol could represent a risk factor for abnormal stress response ([Sherin and Nemeroff 2011](#)). Furthermore, some studies report that PTSD can be averted by hydrocortisone treatment following trauma ([de Quervain 2008](#)), while others suggest that treatment aimed at replicating the normal cortisol secretion pattern is effective ([Aerni et al. 2004](#)). A possible explanation for hypocortisolism in PTSD is that cortisol may interfere with traumatic memory retrieval ([de Quervain and Margraf 2008](#)). A recent intriguing study of intergenerational transmission of susceptibility to PTSD reported differential effects of paternal and maternal PTSD on the offspring of Holocaust survivors ([Yehuda et al. 2014](#)). Offspring with paternal PTSD but no maternal PTSD showed higher methylation of the exon 1<sub>F</sub> promoter of the glucocorticoid receptor (GR-1<sub>F</sub>) gene (*NR3C1*), whereas offspring with both maternal and paternal PTSD showed lower methylation.

## Hypothalamic-Pituitary-Thyroid Axis

---

Despite the well-recognized importance of the hypothalamic-pituitary-thyroid (HPT) axis in clinical psychiatry, it has been far less researched in recent times than the HPA axis. In this important hormonal system, hypothalamic secretion of thyrotropin-releasing hormone (TRH) stimulates the anterior pituitary gland to release thyroid-stimulating hormone (TSH). TSH in turn stimulates

thyroid secretion of triiodothyronine ( $T_3$ ) and thyroxine ( $T_4$ ), which exert negative feedback on the pituitary gland and hypothalamus. There is a well-known association between hypothyroidism and mood disorders, including depression and rapid-cycling bipolar disorder, and between hyperthyroidism and symptoms of anxiety and dysphoria ([Hendrick et al. 1998](#)). Studies of depressed patients have found evidence of changes in the TSH response to TRH, higher levels of antithyroid antibodies, and elevated concentrations of TRH in the CSF ([Musselman and Nemeroff 1996](#)). However, despite these promising findings, a double-blind randomized, placebo-controlled trial of  $T_3$  augmentation of sertraline treatment in patients with MDD found no added benefit from combining  $T_3$  with sertraline ([Garlow et al. 2012](#)).

Studies examining the relationship between HPT axis abnormalities and PTSD have been limited, but there is some evidence of thyroid abnormalities in combat veterans. Elevated  $T_3$  and  $T_4$  were reported in Vietnam veterans diagnosed with PTSD ([Prange 1999](#)), whereas in World War II veterans with more chronic PTSD diagnoses,  $T_3$  was elevated but  $T_4$  levels were normal ([Wang and Mason 1999](#)).

## **Growth Hormone and the Hypothalamic-Pituitary-Somatotrophic Axis**

---

Like the role of the HPT, the role of the hormonal system regulating growth hormone (GH, or somatotropin)—the hypothalamic-pituitary-somatotrophic axis—in mental health has been understudied. GH is synthesized by the anterior pituitary gland and is used in research predominantly as a marker of the integrity of the noradrenergic system following challenge. GH-releasing hormone (GHRH) and somatostatin regulate GH secretion through stimulation and inhibition, respectively, and are themselves regulated by a number of neurotransmitters, including acetylcholine, dopamine,  $\gamma$ -aminobutyric acid (GABA), norepinephrine, and serotonin. GH and insulin-like growth factors exert negative feedback to inhibit GH secretion. Studies of clonidine-induced GH release have documented a blunted GH response in depression that is thought to result from HPA axis changes ([Dinan 1998](#)). Reduced serum levels of GH have been observed in patients with schizophrenia, and reduced pituitary levels of GH have been found postmortem in people with chronic schizophrenia ([Guest et al. 2011](#)). A recent study reported a higher insulin:GH ratio in patients with schizophrenia, their siblings with a mood disorder diagnosis, and their unaffected siblings compared with healthy control participants ([van Beveren et al. 2014](#)).

---

## Prolactin

---

Prolactin is secreted by the anterior pituitary gland in 14 pulses over 24 hours in a circadian pattern consisting of increased pulsation at the time of sleep onset, with the peak level occurring halfway through the sleep period and the

trough level occurring on awakening. Prolactin trough levels are higher during the luteal phase of the menstrual cycle. Dopamine acts at anterior pituitary D<sub>2</sub> receptors to inhibit prolactin secretion, whereas serotonin exerts a stimulatory effect. Studies using serotonin-challenge agents to examine basal prolactin in patients with depression have yielded mixed findings, likely attributable to issues such as methodological difficulties, the complexity of the serotonin system, and the multifactorial nature of depression itself ([Nicholas et al. 1998](#)). A study in antipsychotic-naïve adults identified hyperprolactinemia (which is frequently attributed to iatrogenic causes) in more than 30% of individuals diagnosed as being at risk for psychosis ( $n=43$ ) and more than 20% of those experiencing a first psychotic episode ( $n=26$ ) ([Aston et al. 2010](#)).

---

## Hypothalamic-Pituitary-Gonadal Axis

---

In contrast to the HPT and HPS axes, the hypothalamic-pituitary-gonadal (HPG) axis has been far more widely investigated in relation to mental health. Secretion of the principal gonadal steroids, estrogen and progesterone, is governed by cyclic changes in ovarian follicular and corpus luteum development over the course of the menstrual cycle. Critical to the proper functioning and timing of the monthly hormonal cycle is the pulsatile secretion of gonadotropin-releasing hormone (GnRH). GnRH secretion from the hypothalamus drives the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotropes.

The pulsatile secretion of GnRH is driven by a pulse generator in the arcuate nucleus of the hypothalamus. This pulsatile pattern is critical for the control of serum LH, FSH, and ovulation. LH secretory pulses in the peripheral circulation are used as the marker of GnRH secretory pulses. In humans, the follicular phase of the menstrual cycle is characterized by LH pulses of relatively constant amplitude every 1–2 hours ([Reame et al. 1984](#)).

It has been established that an increased incidence of depression in women ([Weissman and Klerman 1977](#)) extends from adolescence until menopause ([Kessler et al. 1993](#)), suggesting a potential role for ovarian steroids in the etiology of depressive disorders. This hypothesis is supported by evidence that in women with a history of depression, times of rapidly changing gonadal steroid concentrations, such as those occurring premenstrually or postpartum, constitute periods of particular vulnerability to depressive symptoms. Several studies have shown that a history of depression increases the risk of both postpartum “blues” and postpartum MDD ([O’Hara 1986](#); [O’Hara et al. 1991](#)) and that premenstrual hormonal changes may affect mood ([Halbreich et al. 1984](#)). Other studies found a relationship between elevated estrogen and testosterone levels and the rising incidence of depression in girls during adolescence ([Angold et al. 1999](#)).

Premenstrual syndrome (PMS) is one of the best-studied depressive disorders in terms of the effects of ovarian steroids on mood. Studies of follicular, mid-luteal, and late-luteal phases of the menstrual cycle found no significant differences between healthy controls and women diagnosed with PMS ([Reame et al. 1984](#)). The hypothesis that PMS symptoms are related to delayed effects of progesterone on mood prompted several studies of RU486, a progesterone

antagonist. [Schmidt et al. \(1991\)](#) found no reduction in mood symptoms following RU486 creation of an artificial follicular phase during the second half of the menstrual cycle. Furthermore, human chorionic gonadotropin did not reduce mood symptoms; progesterone blockade caused early menses without preventing depression. A subsequent 6-month randomized double-blind, placebo-controlled crossover study also showed no benefit of RU486 on depressive symptoms ([Chan et al. 1994](#)). [Rubinow and Schmidt \(1989\)](#) proposed that PMS is a cyclical mood disorder “entrained” to the menstrual cycle, rather than a disorder caused by changes in ovarian steroids.

Because of the documented increased incidence of depression at critical hormonal transition phases (e.g., postpartum, perimenopause), much speculation has focused on estrogen’s role as a precipitant. Two epidemiological cohort studies ([Cohen et al. 2006](#); [Freeman et al. 2006](#)) also identified an increased incidence of depressive symptoms and MDD during the menopausal transition. Both high and low estrogen levels were associated with depression ([Freeman et al. 2004, 2006](#)), suggesting that estrogen levels may drive depression, and women who showed rapid changes in estrogen (from high to low levels and vice versa) tended to develop depressive symptoms during the perimenopause transition. [Schmidt and Rubinow \(2009\)](#) proposed that in some women, menopausal changes in estrogen secretion may trigger CNS effects that predispose to depression. These authors pointed to evidence that perimenopausal depressive episodes tend to occur during the late menopausal transition ([Steinberg et al. 2008](#)), a phase of estradiol withdrawal ([Santoro et al. 1996](#)). Furthermore, double-blind, placebo-controlled trials of estradiol therapy in perimenopausal women diagnosed with

depression have shown significant improvement in symptoms after 3 weeks of treatment ([Schmidt et al. 2000](#); [Soares et al. 2001](#)). Finally, a randomized double-blind, placebo-controlled trial of the effect of estradiol withdrawal on mood in women with a history of perimenopausal depression documented a recurrence of depressive symptoms during blinded hormone withdrawal ([Schmidt et al. 2015](#)).

Another time of increased vulnerability to depression in women is pregnancy and the postpartum period. Although it is known that this period coincides with a sudden drop in progesterone and estradiol levels, there is limited evidence on how this drop relates to depression onset. A recent systematic review of risk factors for antenatal and postnatal depression identified a wide range of biological, psychological, and social factors in both high- and low-income countries ([Howard et al. 2014](#)). Studies of both animals and humans provide evidence of a subtype of depression associated with 1) sensitivity to reproductive hormone changes; 2) higher rates of depression premenstrually, postnatally, and perimenopausally ([Craig 2013](#); [Schiller et al. 2015](#)); and 3) a personal or family history of postnatal depression ([Cooper and Murray 1995](#); [Forty et al. 2006](#)). Although some studies have reported elevated CRH ([Yim et al. 2009](#)), glucocorticoid, and CRH receptor polymorphisms ([Engineer et al. 2013](#)) and raised leptin levels ([Skalkidou et al. 2009](#)) as risk factors during pregnancy, the relative paucity of literature addressing this clinically significant area underscores the need for replication studies and further research.

In their review of perinatal bipolar disorder, affective psychosis, and schizophrenia, [Jones et al. \(2014\)](#) concluded that most of the evidence supporting a role for hormones in

these disorders has been circumstantial ([Bloch et al. 2003](#)). The reviewers suggested that rather than indicating abnormal hormone levels, postpartum psychotic disorders may indicate abnormal responses to normal perinatal hormone changes ([Bloch et al. 2000](#)). Furthermore, [Jones et al. \(2014\)](#) pointed to evidence of a dysregulated immune-neuroendocrine set point in postpartum psychosis, including monocyte and macrophage overactivity ([Bergink et al. 2013](#); [Weigelt et al. 2013](#)), a finding that requires further investigation.

## Effects of the Hypothalamic-Pituitary-Adrenal Axis on the Hypothalamic-Pituitary-Gonadal Axis

Stress has long been known to inhibit the HPG axis, and there is a well-established association between infertility and high population density. Shortly after the isolation and sequencing of the CRH gene, it was demonstrated in rats that CRH inhibited LH secretion ([Rivier and Vale 1984](#)) and GnRH secretion ([Petraglia et al. 1987](#)), and further primate studies showed inhibition of LH secretion by injection of CRH ([Olster and Ferin 1987](#)).

Studies in ewes found that LH secretory amplitude was inhibited by stress, that the effects of stress were reversed by metyrapone inhibition of cortisol synthesis, and that infusion of stress levels of cortisol could produce inhibition of LH pulse amplitude but not frequency ([Breen et al. 2004](#); [Debus et al. 2002](#)). These data suggest that cortisol, in addition to central CRH, may play a role in LH disruption.

Human studies have linked HPG axis abnormalities to HPA axis activation in anorexia nervosa, exercise-induced amenorrhea, and hypothalamic amenorrhea. In all three syndromes, hypercortisolemia has been observed, indicating overactivity of the HPA axis ([Berga et al. 1989](#); [Casanueva et al. 1987](#); [Hohtari et al. 1988](#); [Loucks et al. 1989](#); [Suh et al. 1988](#); [Villanueva et al. 1986](#)). In all three conditions, exogenous CRH challenge elicits diminished ACTH or cortisol responses, suggesting that high baseline cortisol exerts negative feedback on hormonal effects of CRH ([Berger et al. 1983](#); [Biller et al. 1990](#); [Gold et al. 1986](#); [Hohtari et al. 1991](#)). In anorexia nervosa, the hormonal abnormalities in the HPA and HPG axes are secondary to the weight loss. Weight restriction and low body weight are also observed in exercise-induced amenorrhea, and low body weight has been reported in hypothalamic amenorrhea. Even relatively mild degrees of weight loss in normal-weight or obese patients can lead to disturbances in both of these axes, as manifested by resistance to dexamethasone and by disturbances in menstrual cycle regularity or amenorrhea ([Berger et al. 1983](#); [Edelstein et al. 1983](#); [Pirke et al. 1985](#)). In anorexia nervosa, LH secretory patterns may revert to prepubertal levels of low nonpulsatile secretion or to a pubertal pattern of entrainment of LH secretion to the sleep cycle. Studies by [Reame et al. \(1985\)](#) in women with hypothalamic amenorrhea demonstrated that LH secretion during the follicular phase was slowed to the rate normally observed during the luteal phase.

## Conclusion

---

In this chapter, we have sought to provide an overview of the established findings and the most promising developments in the dynamic field of psychoneuroendocrinology. Following a resurgence of research in this area, the interrelationships among early stressful life events, HPA axis dysregulation, altered immune function, vulnerability to psychiatric disorders, and inadequate response to treatment have become increasingly well characterized, although many findings remain correlational in nature. The growing clinical recognition of the burden of postpartum psychopathology and the associations between reproductive hormone changes and psychiatric disorders has provided further impetus for academic progress in this area. Stressful life events are strongly associated with depression, psychosis, and PTSD, but the relative contributions of genetic, developmental, and environmental factors to an individual's vulnerability have yet to be fully understood.

# CHAPTER 5

## **Brain-Immune System Interactions**

Relevance to the Pathophysiology and Treatment of Neuropsychiatric Disorders

Firdaus S. Dhabhar, Ph.D.

Charles L. Raison, M.D.

Andrew H. Miller, M.D.

**Multidirectional** interactions among psychological factors and the nervous, endocrine, and immune systems form the basis of important physiological pathways that are crucial for maintaining mental and physical health. These multisystem interactions can also mediate the pathological aspects of numerous diseases. Therefore, elucidating psychoneuroendocrine-immune pathways and mechanisms is likely to be critically useful for restoring health in the presence of disease or promoting health in the absence of

disease. In this chapter we begin with an overview of the immune system and introduce its three major functional dimensions. We then go on to describe the effects of behavior, brain, and hormones on immune function and the effects of the immune system on the nervous and endocrine systems and on mental and psychological states. Finally, we discuss the relevance of psychoneuroendocrine-immune interactions for mental health.

## **The Immune Triad: Immunoprotection, Immunopathology, and Immunoregulation**

---

The immune system is a highly distributed physiological system. It consists of primary (bone marrow and thymus), secondary (lymph nodes, spleen, tonsils, and parts of mucosal tissues), and tertiary (most other organs in the body) organs, immune cells or leukocytes (granulocytes, monocytes, T cells, B cells, natural killer cells), and humoral factors (e.g., antibodies, cytokines, complement peptides) that traverse the body through a network of vascular and lymphatic vessels. When discussing immune responses, it is useful to categorize them in terms of their principal cellular and molecular components. For example, innate, adaptive, and helper T cell (e.g., Th1, Th2, Th17) immune responses are all defined in terms of their cellular, cytokine, and humoral components. In addition to these categories, it is also useful to define immune responses in terms of their

integrated functional effects. [Dhabhar \(2009a, 2009b, 2014\)](#) proposed that immune responses be categorized as being immunoprotective, immunopathological, and immunoregulatory/inhibitory. It is important to bear in mind that although such categories provide useful constructs with which to organize ideas, concepts, and models, an overall in vivo immune response is likely to consist of several types of responses with varying amounts of dominance from each category. The composition and nature of an immune response is also affected by—and changes with—time. The three major types of immune responses are defined below in terms of their functional end effects ([Dhabhar 2009a, 2009b, 2014](#)).

*Immunoprotective responses* are defined as those that promote efficient wound healing, eliminate infections and cancer, and mediate vaccine-induced immunological memory ([Dhabhar 2009a, 2009b](#)). Key characteristics of immunoprotection include active immune surveillance, a rapid and robust response on immune activation, and efficient clearance of the activating agent or pathogen, followed by rapid resolution. Immunoprotective responses are critical for completion of the proliferative and remodeling phases of wound healing. Wound healing is important not only for frank wounds (where the initiating event is tissue damage itself) but also for tissue-intrinsic “wounds” (where the initiating event is an immune response precipitated by intracellular infection, during which there can be collateral tissue damage). Different types and combinations of immune response—innate, adaptive, Th1, Th2—can confer immunoprotection, depending on the type of pathogen involved (viral, bacterial, protozoan, fungal, helminthic), on whether the pathogen is intracellular or extracellular, and on the

accompanying wounding conditions (sterile, infected, external, or internal wounds).

*Immunopathological responses* are defined as those that are directed against the self (as in autoimmune diseases such as multiple sclerosis, arthritis, or systemic lupus erythematosus) or against innocuous antigens (asthma, allergies) and responses that are directed against chronic, nonresolving inflammation ([Dhabhar 2009a, 2009b](#)). Immunopathology is also involved in low-level, long-term elevations in local and/or systemic inflammatory mediators (e.g., C-reactive protein or interleukin 6 [IL-6]), which are thought to contribute to disorders such as cardiovascular disease, obesity, and depression ([Dantzer et al. 2008](#); [Maes 1993](#); [Van Gaal et al. 2006](#)).

*Immunoregulatory responses* are defined as those that involve immune cells and factors that regulate (mainly downregulate) the function of other immune cells ([Dhabhar 2009a, 2009b](#)). Although the earlier concept of suppressor T cells became mired in controversy, newer studies suggest that there is an arm of the immune system that functions to inhibit immune responses ([Piccirillo 2008](#); [Simpson 2008](#); [Wing and Sakaguchi 2010](#)). For example, regulatory CD4+ CD25+FOXP3+T cells, IL-10, and transforming growth factor  $\beta$  have been shown to have immunoregulatory/inhibitory functions. The physiological function of these factors is to keep proinflammatory, allergic, and autoimmune responses in check ([Bluestone and Tang 2005](#); [Wing and Sakaguchi 2010](#)). However, it has also been suggested that immunoregulatory/inhibitory factors may suppress anti-tumor immunity and that their presence may be indicative of a negative prognosis for cancer ([Finn 2008](#); [Olson and McNeel 2013](#); [Saul et al. 2005](#); [Whiteside 2014](#)).

---

# Effects of the Brain and Behavior on the Body

---

More than four decades ago, Ader and Cohen showed that an immune response could be modified through classical Pavlovian conditioning ([Ader and Cohen 1975](#)). Numerous studies have confirmed and extended this initial insight and have established beyond argument the ability of brain states to significantly modulate immune system functioning ([Bower and Irwin 2016](#); [Irwin and Rothmundt 2012](#); [Kelley and McCusker 2014](#); [Nemeroff 2013](#); [Padro and Sanders 2014](#); [Quan 2014](#); [Schedlowski et al. 2014](#); [Straub 2014](#)). The majority of these studies have focused on the effects of stress on the immune response ([Dhabhar 2014](#); [Straub et al. 2013](#)).

## Effects of Stress on Immune Function

Even though the word *stress* generally has negative connotations, stress is a familiar and ubiquitous aspect of life, representing a stimulant for some individuals but a burden for many others. Numerous definitions have been proposed for the concept of stress, each focusing on aspects of an internal or external challenge, disturbance, or stimulus; on stimulus perception; or on a physiological response ([Goldstein and McEwen 2002](#); [McEwen 2002](#); [Sapolsky 2005](#)). An integrated definition states that stress is a constellation of events consisting of a stimulus (*stressor*) that precipitates a reaction in the brain (*stress*

*perception and evaluation*) that activates physiological fight-or-flight systems in the body (*biological stress response*) ([Dhabhar and McEwen 1997](#)).

Short-term stress involves changes in stress-related factors that last for minutes to hours, whereas chronic stress involves changes that last for months or years. The only way that a stressor can affect the brain or body is through the biological stress response. Although many factors are involved, the major mediators of stress effects are norepinephrine and epinephrine, which are released by the sympathetic nervous system, and corticotropin-releasing hormone (CRH), adrenocorticotropin, and cortisol, which arise following activation of the hypothalamic-pituitary-adrenal (HPA) axis. Virtually every cell in the body expresses receptors for one or more of these factors. Therefore, stress hormones can induce changes in almost all cells and tissues and inform them about the presence of a stressor. Virtually every type of stressor, ranging from laboratory stressors (e.g., public speaking, mental arithmetic) to life-related stressors (e.g., exercise, process of undergoing surgery, sky diving, bereavement, loneliness, academic examinations), has demonstrated a measurable effect on the immune system ([Dhabhar 2014](#); [Raison et al. 2002](#)).

Although stress has a bad reputation, it is important to recognize that the adaptive purpose of a physiological stress response is to promote survival during fight or flight. Whereas long-term stress is generally harmful, short-term stress can be protective in that it prepares the organism to deal with threats or challenges. It has been proposed that a psychophysiological stress response is one of nature's fundamental survival mechanisms that could be therapeutically harnessed to augment immune function

during vaccination, wound healing, or infection ([Dhabhar 2009a, 2009b, 2014](#); [Dhabhar and McEwen 1999](#); [Dhabhar and Viswanathan 2005](#)). Mechanisms of acute stress-induced immunoenhancement include the following:

1. Subpopulation-specific changes in neutrophil, macrophage, and lymphocyte redistribution ([Dhabhar and McEwen 1997](#); [Dhabhar et al. 2012](#); [Rosenberger et al. 2009](#))
2. Increased leukocyte infiltration into sites of immune activation ([Viswanathan and Dhabhar 2005](#))
3. Increased dendritic cell and macrophage maturation and traffic to draining lymph nodes ([Viswanathan and Dhabhar 2005](#))
4. Enhanced local cytokine production with a key role for  $\gamma$ -interferon ([Dhabhar et al. 2000](#))
5. Enhanced systemic production of cytokines such as IL-1 and IL-6, which is also likely to contribute to enhancement of immune function induced by short-term stress ([Aschbacher et al. 2012](#); [Puterman et al. 2014](#); [Steptoe et al. 2001](#)).

The adjuvant-like immunoenhancing effects of short-term stress may have evolved because many stressful situations (e.g., aggression, accident) result in immune activation (e.g., wounding, infection) and vice versa ([Dhabhar 2014](#); [Puterman et al. 2014](#)). Interestingly, in modern times, many medical procedures involving immune activation (e.g., vaccination, surgery) also induce a stress response. Preclinical findings initially lent support to this hypothesis ([Dhabhar and McEwen 1996](#); [Dhabhar et al. 1995](#); [Viswanathan and Dhabhar 2005](#)) and subsequently were replicated in humans. Clinical studies have demonstrated

that patients undergoing knee surgery who show a robust and adaptive immune cell redistribution profile during the short-term stress of surgery also show significantly enhanced recovery ([Rosenberger et al. 2009](#)). Similarly, preclinical studies initially demonstrated that short-term stress that was experienced during primary ([Blecha et al. 1982](#); [Coe et al. 1989](#); [Dhabhar and Viswanathan 2005](#); [Viswanathan et al. 2005](#); [Wood et al. 1993](#)) or secondary ([Blecha et al. 1982](#); [Dhabhar and McEwen 1996, 1999](#); [Dhabhar et al. 2000](#); [Saint-Mezard et al. 2003](#)) antigen exposure significantly enhanced the ensuing immune response ([Dhabhar 2002](#)). An elegant series of clinical studies has demonstrated that the adjuvant effects of short-term psychological stress, or exercise stress, can enhance vaccine-induced immunity in human subjects ([Edwards et al. 2006, 2007, 2008](#)).

In contrast to short-term stress, chronic or long-term stress can be harmful ([Dhabhar and McEwen 1997](#)). Chronic stress suppresses or dysregulates innate and adaptive immune responses by altering the type 1-type 2 cytokine balance, inducing low-grade chronic inflammation and suppressing the numbers, trafficking, and function of immunoprotective cells ([Dhabhar 2009a, 2009b, 2014](#)). Chronic stress has been shown to increase susceptibility to infections, reduce antibody responses to vaccination, and delay wound healing ([Cohen et al. 1991](#); [Fagundes et al. 2013](#); [Glaser and Kiecolt-Glaser 2005](#); [Irwin 2008](#); [Kiecolt-Glaser et al. 1995](#); [Padro and Sanders 2014](#); [Sanders and Straub 2002](#); [Solomon 1969](#); [Straub et al. 2013](#); [Vitlic et al. 2014](#); [Webster Marketon and Glaser 2008](#)). Chronic stress also has been linked to increased morbidity and mortality in neoplastic diseases (including breast cancer and malignant melanoma), diabetes, and cardiovascular disease ([Antoni et](#)

al. 2006; Ben-Eliyahu et al. 2007; Dhabhar 2014; Evans et al. 2005; Fenton and Stover 2006; Leserman et al. 1999; Lutgendorf and Sood 2011; Raison and Miller 2003a; Saul et al. 2005). In addition to significant personal and health-related costs of chronic stress, the annual economic cost to industry arising from work-related stress in the United States is estimated at more than \$300 billion ([American Psychological Association 2007](#)). Dysregulation of the circadian cortisol rhythm is an important marker that coincides with the deleterious effects of chronic stress ([Dhabhar 2014](#); [Dhabhar and McEwen 1997](#); [Saul et al. 2005](#); [Sephton and Spiegel 2003](#)).

Key factors that determine whether stress enhances or suppresses immune function include the following (for a review, see [Dhabhar 2009a, 2009b; 2014](#)):

1. The effects of stress on immune cell distribution in the body
2. The duration (short [minutes to hours] versus long [weeks to months to years]) of changes in stress-related factors
3. The differential effects of physiological versus pharmacological concentrations of stress hormones and the differential effects of endogenous (e.g., cortisol, corticosterone) versus synthetic (e.g., dexamethasone) hormones
4. The timing of stressor or stress hormone exposure relative to the time of activation and ensuing time course of the immune response

It is important to recognize that factors such as gender, genetics, age, route of administration and nature of the immunizing antigen, and time during the circadian cycle additionally affect immune function and could also affect

the nature of the relationship between stress and immune function. It is also important to bear in mind that it is not the effect of a particular stressor in enhancing or suppressing immune function, but rather the end effect on the immune response, that determines whether stress-immune system interactions have beneficial or harmful effects on health.

## Effects of Depression on Immune Function

Numerous studies have investigated the effects of stress-related disorders, especially major depressive disorder, on immune function ([Antonioli et al. 2012](#); [Blume et al. 2011](#); [Irwin and Miller 2007](#); [Miller and Raison 2016](#)). Despite a significant degree of heterogeneity across individual studies, evidence suggests that patients with major depressive disorder demonstrate a number of immune changes similar to those seen in individuals undergoing chronic and/or severe stress ([Herbert and Cohen 1993](#); [Zorrilla et al. 2001](#)). This is hardly surprising, given the many indices of stress system hyperactivity that are apparent in patients with major depressive disorder, including increased CRH and cortisol production ([Pariante et al. 1995](#)) and augmented sympathetic nervous system activity as manifested in part by increased peripheral blood catecholamines ([Veith et al. 1994](#); [Wong et al. 2000](#)). Enumerative immune changes shared by major depressive disorder and chronic or severe stress include decreases in lymphocytes, B cells, and T cells and increases in the ratio of CD4 to CD8 T cell subsets ([Herbert and Cohen 1993](#)). Shared functional changes include decreases in natural

killer (NK) cell activity and lymphocyte proliferation in response to nonspecific mitogens (Table 5-1) (Herbert and Cohen 1993; Zorrilla et al. 2001). It is important to note, however, that major depressive disorder is a heterogeneous condition, and immune changes are not uniform across all patients. Indeed, inhibited lymphocyte responses tend to be most striking in patients who are older, are hospitalized, or have more severe and/or melancholic types of depression (Miller 1998; Schleifer et al. 1989). In addition, the sleep changes common in depression are known to alter lymphocyte responses, especially NK cell activity (NKCA), even in the absence of other depressive symptoms (Irwin 2015; Irwin et al. 1996). Nonetheless, it does not appear that these factors completely account for the association between major depressive disorder and alterations in measures of the number and function of lymphocyte subsets (Herbert and Cohen 1993; Irwin and Miller 2007).

Evidence suggests that depression, like chronic stress, may impair T cell function in ways that are relevant to disease vulnerability. For example, one study reported that patients with major depressive disorder have a marked decrease in the ability to generate lymphocytes that respond to the herpes zoster virus ([Irwin et al. 1998](#)). Also consistent with impaired T cell function in depression is the observation that depressed patients, especially those with melancholia, demonstrate impaired cell-mediated immunity (CMI), as measured by the delayed-type hypersensitivity response ([Hickie et al. 1993, 1995](#)).

A growing database suggests that depression in both medically healthy and medically ill patients is associated with increased immunopathological proinflammatory responses ([Andrei et al. 2007](#); [Kim et al. 2007](#); [Lespérance et al. 2004](#); [Maes 1999](#); [Miller and Raison 2016](#); [Musselman et al. 2001b](#); [Raison et al. 2006](#)). Findings consistent with inflammatory activation in depression include increased plasma and cerebrospinal fluid (CSF) concentrations of inflammatory cytokines, increased in vitro production of proinflammatory cytokines from stimulated peripheral blood mononuclear cells, increased acute-phase proteins (and decreased negative acute-phase proteins), increased chemokines and adhesion molecules, and increased production of prostaglandins ([Kim et al. 2007](#); [Maes 1999](#); [Raison et al. 2006](#)).

On the basis of meta-analyses, increases in peripheral blood IL-6 and C-reactive protein are two of the most reliable inflammatory biomarkers associated with depression ([Zorrilla et al. 2001](#)). Indeed, careful studies examining IL-6 across the circadian cycle have found that in comparison with control subjects, depressed patients show a reverse circadian pattern of IL-6, with markedly elevated

levels of this cytokine during the morning hours ([Alesci et al. 2005](#)). Of interest, given the role of IL-6 and C-reactive protein in predicting disease outcome in both cardiovascular disorders and diabetes ([Ridker et al. 2000a, 2000b](#)), as well as data indicating that inflammation may play a role in cancer ([Aggarwal et al. 2006](#)), the relationship between depression and activation of the proinflammatory response may provide a mechanism that explains the negative impact of depression on a number of illnesses ([Evans et al. 2005](#)). Moreover, immune activation in major depressive disorder may be involved in several of the pathophysiological changes that are common in the context of depression, including bone loss, insulin resistance, cachexia, increased body temperature, and hippocampal volume loss ([Raison et al. 2006](#)).

It is important to recognize that in the absence of chronic infection, cancer, or immunodeficiency disease, modest elevations in anti-inflammatory cytokines may exert salubrious or health-protective effects by mediating the resolution of inflammatory processes and preventing or antagonizing the damaging effects of prolonged inflammation. In contrast to the attention focused on proinflammatory cytokines, considerably less attention has been accorded to the potential role of anti-inflammatory/immunomodulatory cytokines such as IL-10 in depression. In healthy individuals, there is a regulated balance between pro- and anti-inflammatory cytokines: for example, IL-6 mediates the early phase of the inflammatory process and induces the release of IL-10, which exerts immunoregulatory effects and resolves inflammation ([Daftarian et al. 1996](#); [Fang et al. 2008](#); [Ogawa et al. 2008](#)). The net result of such regulatory relationships is that the immune system can quickly respond to a challenge and

subsequently return to homeostasis once the challenge has ended. Short-term inflammatory reactions in response to immune challenges such as wounding or infection are adaptive and essential for survival, but chronic inflammation is harmful. Interestingly, depression is associated with numerous disorders that are thought to involve chronic inflammation ([Dantzer et al. 2008](#); [Evans et al. 2005](#); [Kiecolt-Glaser and Glaser 2002](#)). These include cardiovascular disease ([Frasure-Smith et al. 2007](#); [McCaffery et al. 2006](#); [Musselman and Nemeroff 2000](#); [Whooley et al. 2007](#)), obesity ([Onyike et al. 2003](#)), rheumatoid arthritis ([Bruce 2008](#); [Zautra et al. 2004](#)), multiple sclerosis ([Triantafyllou et al. 2008](#)), and cancer ([Currier and Nemeroff 2014](#)).

A number of potential factors may contribute to increased proinflammatory responses in depressed patients. One factor that has received special attention is body mass index (BMI). BMI has been reliably correlated with peripheral markers of inflammation, including IL-6, in part related to the capacity of adipocytes to produce inflammatory cytokines ([Schäffler et al. 2007](#)). Of relevance in this regard, an analysis of data from the Third National Health and Nutrition Examination Survey revealed that after adjustment for a multitude of variables, including BMI, there was a strong association between major depressive disorder and elevated levels of C-reactive protein in men but not in women ([Ford and Erlinger 2004](#)). Early life stress is another factor that may be involved. For example, males with current major depressive disorder and a history of high early life stress exhibited significantly greater increases in IL-6 and nuclear factor (NF)- $\kappa$ B DNA binding following a psychosocial stressor compared with nondepressed male control subjects ([Pace et al. 2006](#)).

It has been suggested that an important and relatively underappreciated mechanism for the link between depression and inflammatory disorders may be disruption of the immunoregulatory balance between pro- and anti-inflammatory cytokines ([Dhabhar et al. 2009](#)). The cytokine balance can be tilted toward a proinflammatory milieu because of elevated concentrations of proinflammatory cytokines such as IL-6, lowered concentrations of anti-inflammatory/immunomodulatory cytokines such as IL-10, or a combination of the two. Therefore, in addition to the absolute concentrations of these cytokines, the relative concentrations of pro- and anti-inflammatory cytokines can provide a useful index of the net inflammatory milieu and of immune dysregulation. In keeping with this hypothesis, it has been demonstrated that in comparison with control subjects, depressed subjects manifest significantly lower serum IL-10 concentrations, nonsignificantly higher IL-6 concentrations, and significantly higher IL-6 to IL-10 ratios ([Dhabhar et al. 2009](#)). Furthermore, higher levels of depressive symptoms were significantly related to lower IL-10 concentrations and tended to be related to higher IL-6 to IL-10 ratios but were not significantly related to IL-6 concentrations across the total sample of participants ([Dhabhar et al. 2009](#)). Moreover, control subjects showed a strong positive correlation between serum IL-6 and IL-10 concentrations, which was completely absent (near-zero effect size) in depressed subjects. Although depressed subjects had significantly higher BMIs than did the controls, covarying for BMI (or controlling for BMI) did not alter this finding ([Dhabhar et al. 2009](#)).

Given the anti-inflammatory properties of glucocorticoids ([Rhen and Cidlowski 2005](#)), it might be expected that patients with depression who have decreased

glucocorticoid sensitivity, as manifested by nonsuppression of cortisol on the dexamethasone suppression test (DST), would be especially likely to show signs of immune activation. Some evidence suggests that this is indeed the case. Compared with patients with depression who have normal in vivo glucocorticoid sensitivity, patients who are DST nonsuppressors show increased plasma concentrations of the acute-phase reactant  $\alpha_1$ -glycoprotein, as well as increased in vitro mitogen-stimulated IL-6 production ([Sluzewska 1999](#)). Glucocorticoid resistance, as assessed by the DST, has been associated with poor response to antidepressant treatment ([Holsboer 2000](#)). Of interest in light of the relationship between DST nonsuppression and increased inflammatory activity, study findings suggest that patients with treatment-resistant depression are more likely than patients whose depression is responsive to treatment to show evidence of increased inflammatory activity, including increased plasma concentrations of acute-phase proteins, IL-6, and the soluble receptor for IL-6 (sIL-6r), which synergistically enhances IL-6 activity ([Raison et al. 2006](#); [Sluzewska 1999](#)). Moreover, depressed patients who show reductions in unstimulated tumor necrosis factor alpha (TNF- $\alpha$ ) during antidepressant treatment are more likely to respond than those whose TNF- $\alpha$  remains elevated ([Lanquillon et al. 2000](#)).

## Other Psychiatric Disorders and Immune Function

Some evidence suggests that other stress-related neuropsychiatric conditions—including posttraumatic stress disorder (PTSD), chronic fatigue syndrome (CFS), seasonal

affective disorder, and fibromyalgia—may be associated with immune activation, although these conditions have been less well characterized than major depressive disorder. Patients with combat-related PTSD have been reported to demonstrate increased plasma concentrations of IL-1, increased CSF concentrations of IL-6, and increased expression of genes related to inflammation and NF- $\kappa$ B systems ([Baker et al. 2001](#); [Guardado et al. 2016](#); [Spivak et al. 1997](#)). PTSD following civilian disasters appears to be associated with elevated plasma concentrations of IL-6 and its soluble receptor ([Maes et al. 1999b](#)). PTSD following childhood abuse is associated with enhanced CMI responses ([Altemus et al. 2003](#)). Although not found consistently ([Maes et al. 1999b](#)), both severity of symptoms and duration of illness have been reported to correlate positively with indices of immune activation in PTSD ([R.J. Miller et al. 2001](#); [Spivak et al. 1997](#)).

A growing body of literature suggests that patients exposed to early life trauma may be especially vulnerable to the development of psychophysical disorders (e.g., CFS, fibromyalgia) that are characterized by complaints of chronic pain, fatigue, and cognitive difficulties of unknown etiology ([Heim et al. 1997](#)). Consistent with this vulnerability, these disorders have also been associated with evidence of increased inflammatory activity. For example, it has been reported that both CFS and fibromyalgia are accompanied by an increase in acute-phase reactants and increased plasma concentrations and/or peripheral blood mononuclear cell production of proinflammatory cytokines, including IL-1, IL-6, and TNF- $\alpha$  ([Borish et al. 1998](#); [Cannon et al. 1999](#); [Gupta et al. 1997](#); [Maes et al. 1999a](#)). Of note, one report indicates that seasonal affective disorder, a condition with significant

symptom overlap with CFS and fibromyalgia, may be characterized by increased plasma concentrations of IL-6 ([Leu et al. 2001](#)).

Finally, although the picture is far less clear, there has been speculation that immune system activation may contribute to the pathophysiology of psychotic disorders, including schizophrenia, possibly related to an autoimmune diathesis ([Pearce 2001](#); [Rothermundt et al. 2001](#)). Elevated levels of cytokines and their receptors, including IL-2, sIL-2, and IL-6, have been reported in the blood and CSF of patients with schizophrenia, and a high level of CSF IL-2 has been found to predict subsequent schizophrenic relapse ([Rothermundt et al. 2001](#)). In a related fashion, on the basis of seasonal birth patterns that have been reliably replicated in large epidemiological studies of patients with schizophrenia, consideration has been given to the role of viral infection early in development ([Pearce 2001](#)). These findings are consistent with in utero infections of relevant brain structures, including the hippocampus, during critical periods of development (especially during the second trimester) ([Pearce 2001](#)). Moreover, cross-reactivity between brain antigens and antigens of infectious agents may contribute not only to schizophrenia but also to the neurological and psychiatric complications associated with streptococcal infection (i.e., pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections [PANDAS]) ([Snider and Swedo 2000](#)).

## Mediating Pathways

---

Underlying the ability of the central nervous system (CNS) to affect the immune system is a host of connections between autonomic nervous system (ANS) and neuroendocrine pathways and immune system elements. Immune cells are able to directly respond to brain outflow pathways via receptors for small-molecule neurotransmitters, adrenal and gonadal steroids, hypothalamic-releasing factors, and other neuropeptides ([Raison et al. 2002](#)). Specific receptor densities vary among immune cell types, and these variations correlate with cell sensitivity to a given ligand.

## Autonomic Nervous System

It is well known that sympathetic and parasympathetic pathways within the ANS interact to maintain homeostasis in a variety of physiological states, including regulation of the immune response. In addition to expressing receptors for autonomic and neuroendocrine signaling molecules, immune cells and tissues are innervated by fibers derived from the ANS, together comprising a neural pathway that can reflexively regulate the immune response ([Czura et al. 2007](#); [Downing and Miyan 2000](#); [Miller 1998](#); [Raison et al. 2002](#); [Sanders and Kavelaars 2007](#); [Tracey 2002](#)). The sympathetic branch of the ANS appears able to influence the immune system either by changing the vascular tone and blood flow into lymphoid organs or by directly influencing immune cell function via locally released neurotransmitters, especially norepinephrine, and neuropeptides such as neuropeptide Y, substance P, vasoactive intestinal peptide, calcitonin gene-related peptide, and CRH, which, in turn, interact with specific

receptors on nearby immune cells ([Bellinger et al. 1997](#); [Czura et al. 2007](#)).

In addition to immune regulation by the sympathetic branch, the parasympathetic branch of the ANS has been shown to contribute to the regulation of innate immune responses via an efferent neural signaling pathway referred to as the *cholinergic anti-inflammatory pathway* ([Tracey 2002](#)). The existence of this pathway was initially identified in studies showing that stimulation of the vagus nerve attenuates immune system activation and the physiological signs of septic shock in response to lipopolysaccharide, a key component of gram-negative bacterial cell walls ([Borovikova et al. 2000](#)). Follow-up studies have determined that vagal release of acetylcholine, which in turn interacts with the  $\alpha 7$  subunit of the acetylcholine receptor ( $\alpha 7$ nAChR) on relevant immune cells, is capable of suppressing production of cytokines, including TNF- $\alpha$ , via inhibitory effects on nuclear translocation of NF- $\kappa$ B ([Altavilla et al. 2006](#); [Guarini et al. 2003](#)) and activation of Janus kinase 2 signal transducers and activators of transcriptions (STAT) 3 ([de Jonge et al. 2005](#); [Pavlov and Tracey 2005](#)).

Subsequent studies have established that cytokine production is inhibited by efferent vagal pathways in the context of a variety of inflammatory processes, including myocardial ischemia, hemorrhagic shock, ischemia/reperfusion, and pancreatitis ([Altavilla et al. 2006](#); [Guarini et al. 2003](#); [Mioni et al. 2005](#); [van Westerloo et al. 2006](#); [H. Wang et al. 2004](#)). It also has been shown that both vagus nerve stimulation and  $\alpha 7$ nAChR agonists inhibit production of a number of proinflammatory cytokines, including TNF, IL-1, IL-6, IL-8, and high-mobility group box 1 ([H. Wang et al. 2004](#)). Of note, a specific  $\alpha$ nAChR-

dependent vagus nerve pathway to the spleen has been identified that inhibits proinflammatory cytokine production during endotoxemia and polymicrobial sepsis. Furthermore, both splenectomy and vagotomy interrupt the cholinergic anti-inflammatory response ([Huston et al. 2006](#)). Taken together, these findings suggest that in addition to effects on cellular signaling, there are anatomical and hard-wired components of the cholinergic anti-inflammatory pathway.

## Hypothalamic-Pituitary-Adrenal Axis

In concert with the ANS, the HPA axis serves as a central component of the mammalian stress response system. Although glucocorticoids, which represent the final product of HPA axis activation, have long been viewed as immunosuppressive because of their well-documented ability to suppress inflammation (largely through protein-protein interactions between the glucocorticoid receptor and NF- $\kappa$ B) ([Rhen and Cidlowski 2005](#)), it is increasingly recognized that HPA axis effects on immunity are complex ([Dhabhar 2009a, 2009b, 2014](#); [Dhabhar et al. 1995](#)). This complexity arises from the fact that HPA axis effects on the immune system depend on numerous factors, including the immune compartment that is being assessed, the element of the HPA axis being evaluated (i.e., CRH vs. cortisol), and the duration and timing relative to the immune response and stressor application. Thus, for example, glucocorticoids are known to mediate immune cell redistribution in the body ([Dhabhar et al. 1996, 2012](#)) and to enhance CMI in vivo ([Dhabhar and McEwen 1996](#)) through their effects on lymphocyte trafficking ([Dhabhar 1998, 2009, 2014](#)). Moreover, different HPA axis elements demonstrate

divergent immune system effects. For example, the end result of CRH-induced HPA axis activation is proinflammatory cytokine suppression, yet studies demonstrate that the direct effect of CRH on proinflammatory cytokine production may be stimulatory ([Labeur et al. 1995](#); [Paez Pereda et al. 1995](#)).

Finally, the effect of glucocorticoids on naturalistic measures of immunity, such as cutaneous CMI, depends on both the concentration and the duration of glucocorticoids within the immune compartment under consideration. Thus, low doses of glucocorticoids applied for brief periods have been shown in rodents to stimulate CMI, whereas higher (or more protracted) glucocorticoid exposure suppresses CMI ([Dhabhar 2009a, 2009b, 2014](#); [Dhabhar and McEwen 1999](#)).

CRH applied within the CNS suppresses several measures of immunity, including splenic NKCA, mitogen-stimulated lymphocyte proliferation, and in vivo and in vitro antibody formation, as well as T cell responses to T cell receptor antibody ([Caroleo et al. 1993](#); [Irwin et al. 1988](#); [Labeur et al. 1995](#); [Rassnick et al. 1994](#)). CRH-overproducing mice demonstrate a profound decrease in the number of B cells and severely diminished primary and memory antibody responses ([Stenzel-Poore et al. 1994](#)). These immunosuppressive effects appear to be mediated by stress response outflow pathways activated by CRH, given that blockade of the sympathetic nervous system abolishes CRH effects on NKCA and adrenalectomy obviates CRH effects on lymphocyte proliferation ([Irwin et al. 1988](#); [Labeur et al. 1995](#)). In addition, the B cell decreases in CRH-overproducing mice are consistent with the marked reduction in rodent B cells observed after chronic glucocorticoid exposure ([Miller et al. 1994](#)).

In contrast to its immunosuppressive properties, CRH has also been shown to enhance proinflammatory cytokine production in rodents and humans when administered peripherally or within the CNS. Chronic intracerebroventricular administration of CRH to rats leads to induction of IL-1 $\beta$  messenger RNA (mRNA) in splenocytes, and acute intravenous administration in humans has been reported to cause a fourfold increase in the induction of IL-1 $\alpha$  ([Labeur et al. 1995](#); [Schulte et al. 1994](#)). Similarly, the addition of CRH to in vitro mononuclear cell preparations induces the release of IL-1 and IL-6 ([Leu and Singh 1992](#); [Paez Pereda et al. 1995](#)). Both chronic and acute CRH infusion have also been reported to increase production of the immunoregulatory cytokine IL-2 in humans and rodents ([Labeur et al. 1995](#); [Schulte et al. 1994](#)). In addition to potential proinflammatory activities of CRH within the CNS, peripheral production of CRH has been demonstrated in inflammatory diseases such as ulcerative colitis and arthritis, in which it appears to act as a local proinflammatory agent ([Karalis et al. 1997](#); [Nishioka et al. 1996](#)).

Of all neurotransmitters or hormones known to modulate immune functioning, the actions of glucocorticoids, although complicated, are probably the best understood ([Raison et al. 2002](#)). Identified effects of glucocorticoids on the immune (and inflammatory) system include the following:

- Modulation of immune cell trafficking throughout the body ([Dhabhar et al. 1995](#))
- Enhancement of CMI by physiological concentrations of endogenous glucocorticoids ([Dhabhar and McEwen 1999](#);

[Dhabhar 2009a, 2009b, 2014](#))

- Promotion of Th2 (antibody) responses ([Elenkov and Chrousos 1999](#))
- Modulation of cell death (i.e., apoptosis) pathways ([McEwen et al. 1997](#))
- Inhibition of arachidonic acid pathway products (e.g., prostaglandins) that mediate inflammation and illness symptoms (e.g., fever) ([Goldstein et al. 1992](#))
- Inhibition of T cell- and NK cell-mediated cytotoxicity ([Raison et al. 2002](#))
- Inhibition of cytokine production and function through interaction of glucocorticoid receptors with transcription factors (NF- $\kappa$ B in particular), which in turn regulate the expression of cytokine genes and/or cytokine-inducible genes ([McKay and Cidlowski 1999](#))

Although glucocorticoids may actually enhance certain aspects of naturalistic immune functioning when produced for brief periods at low to moderate doses in the context of acute and/or mild stress, glucocorticoids in general play a primary role in restraining excessive or prolonged inflammatory activation ([Munck 1989](#)). This property has long been exploited by modern medicine for the treatment of autoimmune and other chronic inflammatory conditions, with the result that glucocorticoids remain a cornerstone of our anti-inflammatory armamentarium. Consistent with their pharmacological uses, glucocorticoids have been shown to be essential for inflammatory regulation in response to immune system activation. For example, neutralization of endogenous glucocorticoid function results in increased pathology and mortality in rodents exposed to lipopolysaccharide or to other inflammatory stimulators such as streptococcal cell wall antigen or myelin basic

protein ([Bertini et al. 1988](#); [Sternberg et al. 1989](#)). Similarly, rodents that have been rendered glucocorticoid deficient by adrenalectomy have markedly increased death rates following infection with murine cytomegalovirus, an effect that arises from unrestrained activity of the proinflammatory cytokine TNF- $\alpha$  ([Ruzek et al. 1999](#)).

## Effects of the Immune System on the Brain and Behavior

---

### Immune System-to-Brain Signaling Pathways

The field of psychoneuroimmunology is based on the existence of bidirectional communication pathways between the nervous, endocrine, and immune systems ([Ader 2007](#); [Miller et al. 2000](#)). This implies that just as the CNS is capable of modulating immunity, the immune system can alter functioning within the CNS. Although researchers historically were first interested in pathways by which the brain affects immunity, the past 10–15 years have seen a groundswell of interest in the ways in which the immune system contributes to the development of psychopathology ([Capuron and Miller 2011](#); [Steinberg et al. 2015](#)).

Underpinning this growing interest is an increasing appreciation for the multiple ways in which proinflammatory cytokines are able to signal the brain and change CNS function ([Table 5-2](#)). Although the brain was historically considered an “immune privileged” organ,

protected from immune system activity by the blood-brain barrier, it is now clear that cytokines released in the periphery rapidly affect CNS functioning via at least four pathways that are not mutually exclusive (see [Table 5-2](#)) ([Banks 2006](#); [Banks et al. 1995](#); [Maier et al. 1998](#); [Plotkin et al. 1996](#); [Quan 2006, 2014](#); [Raison et al. 2002](#); [Rivest et al. 2000](#)).

---

**TABLE 5-2. Evidence that cytokines can alter central nervous system function**

---

1. Cytokines released peripherally have access to the brain.
    - Passage through leaky regions in the blood-brain barrier (e.g., circumventricular organs)
    - Active transport
    - Activation of intermediary cell types (e.g., endothelial cells) that produce relevant second messengers (e.g., prostaglandins, nitric oxide)
    - Transmission of cytokine signals through afferent nerve fibers (e.g., vagus)
  2. A cytokine network exists within the brain.
    - Glia (especially microglia) and neurons express/produce cytokines and express cytokine receptors
  3. Cytokines have effects on neurotransmitter turnover, neuroendocrine function, synaptic plasticity, and behavior (sickness behavior).
- 

Once proinflammatory cytokines have gained access to the CNS through any of the routes outlined in [Table 5-2](#), the inflammatory signal appears to be amplified by a cytokine network within the brain itself ([Quan et al. 1999](#)).

It has already been noted that cytokines produced in the periphery stimulate the production of proinflammatory cytokines, such as IL-1, IL-6, and TNF- $\alpha$ , in a number of brain regions ([Dantzer and Kelley 2007](#); [Gatti and Bartfai 1993](#); [Layé et al. 1994](#); [Quan 2006, 2014](#); [Quan et al. 1999](#)). Receptors for proinflammatory cytokines are found in the brain, especially in areas of particular importance to homeostatic and emotional regulation, such as the hypothalamus and hippocampus ([Benveniste 1998](#)). Among neural cells, activated microglia are capable of producing significant numbers of proinflammatory cytokines, which in turn are potent activators of glial cells ([Schöbitz et al. 1994](#)). Of interest, growing evidence suggests that nonimmunological stressors can induce cytokine expression in the brain, an effect likely mediated by stress-induced activation of microglia ([Frank et al. 2007](#)). These data suggest that CNS cytokine pathways may participate in an organism's response to a wide variety of environmental perturbations. Consistent with this finding, proinflammatory cytokines have been implicated in the modulation of circadian functioning, especially the sleep-wake cycle ([Hohagen et al. 1993](#); [Opp 2005](#)).

## Sickness Behavior and the Development of Depression in the Medically Ill

It has long been known that major depressive disorder, as well as milder forms of mood disturbance, is many times more common in people with medical illness than in the general population ([Evans et al. 1999](#)). Although this higher

incidence is often ascribed to the overwhelming psychological stress that serious illness engenders, more recent theories have suggested that the immune system activation that typically accompanies medical illness may itself biologically predispose these patients to depression ([Dantzer et al. 2008, 2011](#); [Raison and Nemeroff 2000](#); [Udina et al. 2014](#)). Evidence for this theory comes from the observation that rates of depression are significantly elevated in a wide variety of medical conditions, including inflammatory and autoimmune disorders such as multiple sclerosis and rheumatoid arthritis, as well as in illnesses such as cardiovascular disease, diabetes, and cancer, which are increasingly being recognized as having an important inflammatory component ([Aggarwal et al. 2006](#); [Blake and Ridker 2002](#); [Currier and Nemeroff 2014](#); [Dantzer et al. 2008, 2011](#); [Evans et al. 2005](#)). Moreover, prospective studies of conditions characterized by episodic immune dysregulation, such as multiple sclerosis or herpes infection, typically find that depression immediately precedes, rather than follows, episodes of disease exacerbation, suggesting that depressive symptoms associated with these conditions may result from underlying immune system activity rather than from a psychological reaction to exacerbation of the illness ([Foley et al. 1992](#); [Hickie and Lloyd 1995](#)). Finally, as noted in the subsection “Effects of Depression on Immune Function,” numerous researchers have shown that plasma concentrations of proinflammatory cytokines are significantly higher in medically ill patients with major depressive disorder compared with similar patients without a mood disorder ([Raison et al. 2006](#)). For example, depressed patients with cancer show elevations in IL-6 ([Currier and Nemeroff 2014](#); [Musselman et al. 2001b](#)), and depressed patients with

acute coronary syndromes or chronic heart failure show elevations in C-reactive protein ([Andrei et al. 2007](#); [Lespérance et al. 2004](#)).

More direct evidence that inflammatory processes may contribute to psychopathology, especially in the context of medical illness, comes from many studies in humans and animals demonstrating that administration of proinflammatory cytokines reliably induces changes in mood, cognition, and behavior similar to those commonly observed in patients with mood and anxiety disorders, as well as in psychophysical conditions such as CFS and fibromyalgia ([Dantzer and Kelley 2007](#); [Raison et al. 2006](#)). This constellation of immune-induced changes, referred to as *sickness syndrome* or *sickness behavior*, consists of dysphoria, anhedonia, fatigue, social withdrawal, hyperalgesia, and cognitive and sleep disturbances, as well as decreased appetite and libido ([Dantzer et al. 2008, 2011](#); [Kent et al. 1992](#)). Although seen in response to infection, the full syndrome can be reproduced in animals and humans by administration of innate immune cytokines, such as interferon-alpha (IFN- $\alpha$ ), IL-1, TNF- $\alpha$ , and IL-6, as well as IL-2, even in the absence of infection ([Raison et al. 2002](#)).

Blocking cytokine activity with an IL-1 receptor antagonist,  $\alpha$ -melanocyte-stimulating hormone, or IL-10 diminishes or prevents sickness behavior in laboratory animals, even when such behavior develops as a result of psychological stress ([Milligan et al. 1998](#)). Similarly, etanercept, a novel agent that blocks TNF- $\alpha$  activity, has been reported to improve energy and overall emotional functioning in patients with rheumatoid arthritis, a condition characterized by increased proinflammatory cytokine activity ([Bortolato et al. 2015](#); [Mathias et al. 2000](#);

[Schmidt et al. 2014](#)). TNF antagonists have recently been shown to reduce depressive symptoms in patients with various autoimmune conditions ([Fleming et al. 2015](#); [Persoons et al. 2005](#); [Tyring et al. 2006](#)). Further evidence that cytokine-induced behavioral toxicity is related to major depressive disorder comes from studies showing that in humans and animals, antidepressants are able to abolish or attenuate the development of sickness behavior in response to cytokine administration ([Musselman et al. 2001a](#); [Yirmiya et al. 2001](#)).

## Pathways by Which Inflammatory Cytokines Produce Neuropsychiatric Disturbance

In keeping with the observation that antidepressants mitigate emotional and behavioral symptoms resulting from immune system activation, significant evidence demonstrates that inflammatory cytokines affect neurotransmitters and neuroendocrine pathways that are regulated by currently available antidepressants and that have been implicated in the pathophysiology of depression and other stress-related neuropsychiatric disorders. It is increasingly recognized that these effects on the CNS and its outflow pathways may provide a physiological basis for the observation that immune activation frequently produces neuropsychiatric disturbance ([Miller and Raison 2016](#)) ([Table 5-3](#)).

## **Effects of Inflammatory Cytokines on Monoamine Neurotransmitters**

In laboratory animals, acute intracerebral administration of IL-1 produces a rapid and significant increase in norepinephrine and serotonin (5-hydroxytryptamine [5-HT]) turnover in several brain regions ([Linthorst et al. 1995a, 1995b](#)). Very little is known about the effect of chronic proinflammatory cytokine exposure on the functioning of monoamine systems in either animals or humans. However, cytokines, including IFN- $\alpha$ , have been shown to diminish 5-HT availability as a result of cytokine-mediated enhancement of the activity of indoleamine 2,3-dioxygenase (IDO), an enzyme that shunts tryptophan metabolism away from 5-HT and toward kynurenine and quinolinic acid, which are known to have neurotoxic properties ([Dantzer and Kelley 2007](#); [Raison et al. 2006](#)). Tryptophan is the primary precursor of 5-HT, and tryptophan depletion has been associated with the precipitation of mood disturbances in vulnerable patients ([Moore et al. 2000](#)). Moreover, significant evidence suggests that serotonergic neurotransmission is decreased in many patients with depression ([Owens and Nemeroff 1998](#)). It has also been shown that proinflammatory cytokines, via p38 mitogen-activated protein kinase

(MAPK)-linked pathways, can increase the expression and function of synaptic reuptake pumps for serotonin (and norepinephrine), potentially further contributing to reduced synaptic availability of mood-relevant monoamines (Zhu et al. 2005, 2006).

Of interest, the development of major depressive disorder in the context of chronic IFN- $\alpha$  treatment has been shown to correlate closely with decreased plasma concentrations of tryptophan, possibly as a result of increased IDO activity, consistent with the idea that cytokine-induced decrements in 5-HT availability may contribute to the development of depression (Capuron et al. 2002b). Furthermore, treatment with the selective serotonin reuptake inhibitor (SSRI) paroxetine attenuates the behavioral consequences of IFN- $\alpha$ -mediated tryptophan depletion (Capuron et al. 2003a). In addition to the effects of chronic cytokine exposure on serotonergic transmission, both IL-2 and IFN- $\alpha$ , when they are administered chronically, have been reported to alter dopamine metabolism, and IFN- $\alpha$  has been shown to lead to altered metabolic activity in brain regions high in dopaminergic neurocircuits, including the basal ganglia (Capuron et al. 2007; Lacosta et al. 2000; Shuto et al. 1997).

## Effects of Inflammatory Cytokines on the Thyroid Axis

Medical illness is often associated with a state of functional thyroid deficiency known as *euthyroid sick syndrome* (Papanicolaou 2000). In its early stages, euthyroid sick syndrome is characterized by normal thyroid-stimulating hormone and thyroxine (T<sub>4</sub>) levels but reduced levels of triiodothyronine (T<sub>3</sub>), which is the more biologically active

form of thyroid hormone. In later stages of euthyroid sick syndrome,  $T_4$  levels are also reduced. Evidence suggests that proinflammatory cytokines promote this condition through direct effects on the thyroid gland, as well as through inhibition of enzymes responsible for peripheral conversion of  $T_4$  to  $T_3$ , especially in the liver ([Papanicolaou 2000](#)). It is well known that decreased thyroid functioning is associated with emergence of depressive symptoms, and functional abnormalities of the thyroid axis are found in many patients with major depressive disorder who do not have clinically obvious thyroid disease ([Musselman and Nemeroff 1996](#)).

### **Effects of Inflammatory Cytokines on the Hypothalamic-Pituitary-Adrenal Axis**

Inflammatory cytokines have well-described effects on the HPA axis that are consistent with changes frequently seen in patients with major depressive disorder, including increased production of CRH and cortisol and decreased tissue sensitivity to glucocorticoid hormones ([Capuron et al. 2003a](#); [Hasler et al. 2004](#); [Pace et al. 2007](#); Silverman et al. 2005). Although cytokines have been shown to be capable of activating the HPA axis at multiple levels, with a resultant increase in glucocorticoid release, significant evidence suggests that a major final common pathway for cytokine activation involves stimulation of CRH production in the paraventricular nucleus of the hypothalamus ([Besedovsky and del Rey 1996](#)). Several lines of evidence suggest that this increase in CRH activity may contribute to cytokine-induced depression or sickness behavior ([Miller and Raison 2016](#)). CRH has behavioral effects in laboratory animals that are similar to those seen in patients with depression

and/or sickness behavior, including alterations in appetite, activity, and sleep ([Owens and Nemeroff 1991](#)). Patients with major depressive disorder frequently demonstrate increased CRH production, as assessed by increased CRH in CSF, increased mRNA in the paraventricular nucleus, downregulated frontal CRH receptors, and a blunted adrenocorticotrophic hormone response to CRH challenge (likely reflecting downregulation of pituitary CRH receptors) ([Owens and Nemeroff 1993](#)).

Agents that block the CRH type I receptor have been shown to have antidepressant and anxiolytic effects in humans ([Zobel et al. 2000](#)). In laboratory animals, blocking CRH reverses some of the behavioral sequelae of proinflammatory cytokine administration ([Dantzer 2001](#)). Indirect evidence for a role of CRH in cytokine-induced depression in humans comes from a study in which individuals who subsequently developed depression during IFN- $\alpha$  administration exhibited significantly higher adrenocorticotrophic hormone and cortisol responses to the first injection of IFN- $\alpha$  compared with control subjects ([Capuron et al. 2003b](#)). These findings suggest that sensitized CRH pathways may serve as a vulnerability factor for cytokine-induced behavioral changes.

In addition to direct stimulatory effects on CRH within the CNS, in vivo and in vitro studies suggest that inflammation may induce resistance to circulating glucocorticoids in nervous, endocrine, and immune system tissues ([Miller and Raison 2016](#); [Pariante and Miller 2001](#); [Raison and Miller 2003b](#)). This effect is of great potential relevance, given the high rates of relative glucocorticoid resistance in HPA axis tissues (as assessed in vivo with the DST or the dexamethasone-CRH stimulation test) and the immune system (as measured in vitro) found in patients with major

depressive disorder as well as in rodents and humans exposed to chronic and/or severe stressors ([Holsboer 2000](#)). Also supporting a role for cytokines in the induction of glucocorticoid resistance is the observation that many chronic inflammatory conditions, including steroid-resistant asthma, rheumatoid arthritis, multiple sclerosis, and HIV infection, are characterized by a decrease in sensitivity to glucocorticoids ([Raison et al. 2002](#)). In HIV infection, glucocorticoid resistance has been shown to correlate with increased IFN- $\alpha$  plasma levels ([Norbiato et al. 1998](#)).

There are several mechanisms by which proinflammatory cytokines might disrupt glucocorticoid receptor (GR) function and contribute to glucocorticoid resistance. In addition to downregulating the expression of GR protein, proinflammatory cytokines have been found to increase the expression of the inert  $\beta$  isoform of the GR ([Oakley et al. 1996](#)). Exposure of cells that constitutively express both GR- $\alpha$  (the active isoform) and GR- $\beta$  to either TNF- $\alpha$  or IL-1 $\beta$  in vitro results in a marked increase in GR- $\beta$  production, which is associated with the development of glucocorticoid resistance, as evidenced by a significant reduction in dexamethasone-stimulated activity of a GR-sensitive reporter gene in cytokine-treated cells ([Webster et al. 2001](#)). That overproduction of the negative GR- $\beta$  isoform has a clinically relevant effect on glucocorticoid sensitivity is suggested by several studies documenting that patients with a variety of inflammatory and immune system disorders, including asthma, ulcerative colitis, and chronic lymphocytic leukemia, whose conditions are resistant to steroid treatment demonstrate a significantly increased GR- $\beta$  to GR- $\alpha$  ratio ([Honda et al. 2000](#); [Leung 1997](#); [Shahidi et al. 1999](#); [Sousa et al. 2000](#)).

Another mechanism by which inflammatory cytokines may attenuate GR signal transduction and thereby cause glucocorticoid resistance is through induction of inflammatory signaling pathways that directly influence GR function ([Pace et al. 2007](#)). For example, adding IL-1 $\alpha$  to an in vitro preparation of mouse fibroblast cells has been shown to suppress the ability of dexamethasone to induce translocation of the GR from the cytoplasm to its site of action in the nucleus ([Pariente et al. 1999](#)). This IL-1 $\alpha$ -mediated blockade of GR translocation from the cytoplasm to the cellular nucleus inhibits GR activity, as indicated by a decrease in the ability of dexamethasone to activate a glucocorticoid-sensitive reporter gene construct. One of the signaling pathways involved in this effect is p38 MAPK, which has been shown to phosphorylate the GR ([X. Wang et al. 2004](#)). Other inflammatory signaling pathways—including NF- $\kappa$ B, Jun N-terminal kinase (JNK), and STAT5—have also been shown to alter GR function ([Pace et al. 2007](#)).

## Effects of Anti-Inflammatory Agents on Depression

Given that inflammatory factors have been shown to contribute to depression, it has been proposed that anti-inflammatory agents may also have antidepressant actions. It appears that this is the case for patients with inflammatory disorders (e.g., psoriasis, ankylosing spondylitis) who also show increased levels of depression ([Arisoy et al. 2013](#); [Fleming et al. 2015](#); [Krishnan et al. 2007](#); [Tyring et al. 2006](#)) and patients with depression who also show increased levels of proinflammatory markers

([Köhler et al. 2014](#); [Raison et al. 2013](#)). However, anti-inflammatory medications do not appear to have antidepressant effects for patients who do not show increased levels of inflammation. Indeed, the use of anti-inflammatory agents in such patients may actually impair the placebo effect that is thought to be important for antidepressant effectiveness ([Miller and Raison 2016](#); [Raison et al. 2013](#)). Given these findings, insightful reviews have highlighted the need for elucidating markers to identify subgroups of depressed patients in whom anti-inflammatory agents might have antidepressant activity ([Miller and Raison 2016](#); [Schmidt et al. 2016](#)).

## Antidepressants and the Immune System

The term *antidepressant* has been depicted more than once as a misnomer, given the wide spectrum of activity evinced by these pharmacological agents. Adding to this activity spectrum are findings that antidepressants have clear immunomodulatory effects in animals and humans. In general, antidepressants have been found to decrease immune responsiveness ([Eyre et al. 2016](#); [Kenis and Maes 2002](#); [Schmidt et al. 2016](#)). Because of this effect, antidepressant agents may be of benefit for a wide range of symptoms that arise in the context of immune activation. Of special interest, given the ability of inflammatory cytokines to induce sickness behavior and/or major depressive disorder, a number of antidepressants have been reported to attenuate proinflammatory cytokine production, not just from peripheral immune cells ([Maes 1999](#)) but also from within the CNS, where the tricyclic antidepressant

desipramine has been reported to diminish TNF- $\alpha$  release within the locus coeruleus ([Ignatowski and Spengler 1994](#)). Also of interest in this regard, the antidepressant efficacy of desipramine in rats during the forced-swim test has been shown to be dependent on reductions in neuronal production of TNF- $\alpha$  and can be reversed by coadministration of exogenous TNF- $\alpha$  with the antidepressant ([Reynolds et al. 2004](#)). Desipramine has also been shown to reduce peripheral TNF- $\alpha$  production in response to lipopolysaccharide administration—an effect that was associated with abrogation of the depressive-like behavioral effects of lipopolysaccharide ([Shen et al. 1999](#)). The heterocyclic antidepressant bupropion has similarly been noted to markedly diminish TNF- $\alpha$  production following lipopolysaccharide administration in mice ([Brustolim et al. 2006](#)). Of note, concomitant with attenuating proinflammatory cytokine production, antidepressants enhance production of the anti-inflammatory cytokine IL-10 ([Maes et al. 1999d](#)).

In addition to potential direct effects on cytokine production, antidepressants affect neuroendocrine and neurotransmitter systems in ways known to diminish inflammatory activity. For example, all antidepressants appear to downregulate the overproduction of CRH and cortisol that frequently occurs in the context of major depressive disorder. Much evidence suggests that this downregulation results from the ability of antidepressants to enhance glucocorticoid signaling via increased glucocorticoid receptor functioning, which in turn leads to restoration of glucocorticoid-mediated inhibitory control of the HPA axis ([Pariante and Miller 2001](#)). Because CRH has been shown to directly stimulate proinflammatory cytokine production, antidepressants may modulate inflammatory

activity in part by diminishing CRH production. Glucocorticoid receptors, in addition to inhibiting CRH release in the hypothalamus, also mediate the well-characterized anti-inflammatory properties of glucocorticoids. It is likely that antidepressants decrease inflammatory activity in part via their ability to potentiate glucocorticoid receptor functioning ([Pariente and Miller 2001](#)). Antidepressants also normalize the hyperactivity of the locus coeruleus and sympathetic nervous system frequently seen in major depressive disorder ([Ressler and Nemeroff 1999](#)). Because catecholamines have been shown to enhance proinflammatory activity, the normalizing effect of antidepressants on catecholaminergic functioning would be expected to result in diminished inflammatory activity. Finally, antidepressants are known to enhance functioning in intracellular second-messenger systems (such as the cyclic adenosine monophosphate cascade) known to suppress the activation of genes that encode for the production of proinflammatory cytokines ([Duman et al. 2001](#)).

It is clear from studies in laboratory animals and humans that antidepressants effectively diminish many physical, emotional, cognitive, and behavioral symptoms that arise in the context of immune system activation ([Capuron et al. 2002a](#)). In rodents, pretreatment with antidepressants has been shown to prevent the development or reduce the severity of sickness behavior in response to pathogen or cytokine exposure ([Yirmiya et al. 2001](#)). In humans, pretreatment with an antidepressant has been shown in a double-blind, placebo-controlled trial to significantly reduce the development of major depressive disorder among patients receiving high doses of the proinflammatory cytokine IFN- $\alpha$  for the treatment of malignant melanoma

([Musselman et al. 2001a](#)). In this study, 45% of patients receiving placebo developed major depressive disorder within 3 months of starting IFN- $\alpha$ , compared with only 11% of those receiving the SSRI paroxetine. Of interest, however, paroxetine was not equally efficacious for all of the symptoms associated with sickness behavior. Specifically, paroxetine significantly reduced the symptoms of depressed mood, anxiety, and poor cognitive functioning but was no more effective than placebo in reducing somatic or neurovegetative symptoms, such as fatigue and anorexia, suggesting that these symptom domains may have nonoverlapping etiologies ([Capuron et al. 2002a](#)). Consistent with this finding, neurovegetative symptoms tended to develop early (and to persist) in the course of IFN- $\alpha$  treatment in the majority of patients, whereas symptoms of depressed mood, anxiety, and cognitive disturbance tended to develop insidiously over weeks or months of treatment in a smaller percentage of patients ([Trask et al. 2000](#)). The success of pretreatment strategies in preventing the development of neuropsychiatric disorders in medically ill patients at high risk for mood disorders is intriguing and suggests that the use of prophylactic antidepressants should be considered in other medical contexts, such as for patients about to undergo treatment with radiation and/or chemotherapy, as well as for patients about to undergo major surgery.

There are also data to suggest that antipsychotics, although not as well studied as antidepressants, may have immunological effects relevant to their mechanism of action. Intriguing in this regard is a study demonstrating increased antipsychotic efficacy in patients with schizophrenia treated with the combination of the cyclooxygenase-2 inhibitor celecoxib (an anti-inflammatory drug)

and risperidone versus risperidone alone ([Müller et al. 2002](#)). It has also been suggested that proinflammatory factors are elevated in the systemic circulation during the first episode of schizophrenia and that antipsychotic treatment induces a decrease in these factors ([Stefanović et al. 2015](#)). However, other studies have not observed anti-inflammatory effects of antipsychotics ([Fernandes et al. 2016](#)).

## Conclusion

---

It is important to appreciate that mental and physical health are maintained through multidirectional interactions among psychological factors and the nervous, endocrine, and immune systems and other physiological systems of the body. Thus, it should come as no surprise that dysregulated multisystem interactions are often involved in mediating the underlying pathology of numerous diseases. In this chapter we have reviewed a few important examples of ways in which the nervous and endocrine systems affect immune function and the ways in which the immune system in turn affects the endocrine and nervous systems and behavior in the context of health and disease. Much work remains to be done to further elucidate mechanisms and translate findings from bench to bedside. However, elucidation of psychoneuroendocrine-immune pathways and mechanisms is likely to be critically useful for restoring health in the presence of disease or promoting health in the absence of disease.

## CHAPTER 6

# Principles of Pharmacokinetics and Pharmacodynamics

C. Lindsay DeVane, Pharm.D.

Drugs may be taken as single doses on an occasional basis to mitigate a temporary condition. Alternatively, drugs may be taken by patients daily for the rest of their lives to prevent or treat chronic disease. The usual duration of drug therapy is somewhere between these extremes. The amount of drug and the frequency with which it is taken define a dosage regimen. When a new drug or formulation is marketed, dosing guidelines accompanying the product are based on results from a variety of experimental and clinical studies. An integral component of drug development is the investigation of pharmacokinetic and pharmacodynamic properties. An understanding of basic pharmacokinetic/pharmacodynamic principles can aid the investigator in designing studies to

gain the optimal insight from collected data. Understanding these principles also benefits the clinician in helping to develop precision drug dosage regimens to achieve therapeutic goals for individual patients.

*Pharmacokinetics* is defined as the study of the time course of drugs and their metabolites through the body. A typical human study samples blood for laboratory determination of drug concentration in plasma at multiple timed intervals following administration of an oral drug dose. Computer analyses of these data generate estimates of the fundamental pharmacokinetic parameters, including absorption rate, elimination rate, area under the plasma drug concentration versus time curve (AUC), and drug clearance. These estimates can then be used to predict the plasma drug concentration that would be achieved in that individual from various dosage regimens using different-sized doses administered at selected intervals. The results from rigorously studying a small number of individuals are applied to larger populations by assuming that the drug disposition characteristics of the intensively studied population are representative of the larger patient population who will eventually receive the drug. Such data are useful to achieve a minimum plasma drug concentration with multiple-dose regimens when a threshold for pharmacological effects can be defined, or for avoiding excessive drug plasma concentrations that may be associated with adverse events. However, the results of a pharmacokinetic study per se have only limited utility unless they are paired with pharmacodynamic data.

*Pharmacodynamics* is defined as the study of the time course and intensity of the pharmacological effects of drugs. Although pharmacodynamic effects can be recorded following a drug administration, the most useful data will be

derived from studies that record both the drug concentration in a biological fluid (blood, urine, or cerebrospinal fluid [CSF]) and simultaneous measures of a pharmacological effect of interest. With these data, the relationship between drug concentration and effect can be defined so that drug dosage regimens can be designed to achieve a target concentration associated with a desired outcome. Thus, the goal of pharmacokinetic/pharmacodynamic studies is to inform dosing to achieve specific degrees of desired pharmacological effects while avoiding undesirable effects.

The dose and the frequency of dosing necessary to produce the desired pharmacological response from psychoactive drugs differ widely among patients. This variability in the drug dose-effect relationship is not surprising, given the large differences in patients' physiology, ages, range of severity of illness, activity of drug metabolizing enzymes and transporters, renal function, and other variables. The sources of variability can be characterized as pharmacokinetic, pharmacodynamic, or pharmacogenomic. Genetic variability in the form of polymorphic genes controlling the transcription of proteins involved in drug-metabolizing enzymes, drug transporters, and drug targets is a substantial determinant of pharmacokinetic/pharmacodynamic variability. An integrated relationship among these sources of variability is shown as [Figure 6-1](#). An understanding of the relative contribution of each of these sources of variability to the overall dose-effect relationship is an overarching goal in the drug development process for individualizing dosage regimens for specific patients.

**FIGURE 6-1.** Pharmacokinetic, pharmacodynamic, and pharmacogenomic variability as determinants of the dose-effect relationship.

The interface between pharmacokinetics and pharmacodynamics, where drugs interact with molecular targets at an effect site (see [Figure 6-1](#)), is a focus of research. Experimental approaches that separate pharmacokinetic and pharmacodynamic components of the dose-effect relationship have shown that pharmacodynamic variability is a significant contributor in drug response. Identifiable sources of variability include sex, age, body temperature (fever), pregnancy, blood volume, fluid or electrolyte balance, and drug-drug interactions. The ability to link drug concentrations with pharmacodynamic effects using mathematical models has improved greatly in recent years. Population pharmacokinetic/pharmacodynamic modeling enables the relationship between drug concentration and effect to be defined in individuals from vulnerable populations such as children, pregnant women, and the elderly, where only sparse data may be available ([Akil et al. 2016](#); [Bies et al. 2004](#)). Covariants such as age,

gender, genotype of drug-metabolizing enzymes and transporters, and concomitant treatment with other drugs can be easily incorporated into these models and tested for their significance in influencing drug concentration and effects ([DeVane et al. 2006](#)). The mechanisms whereby pharmacodynamic variation occurs have been elusive. It is increasingly accepted that differences in the expression of multiple genes involved in drug targets is a contributor to pharmacodynamic variability.

In this chapter I present basic principles of pharmacokinetics and explain how they interface with pharmacodynamics to provide insight into observed dose-effect relationships. The interface of pharmacokinetics/pharmacodynamics with pharmacogenomics is an essential component of variability in drug dose-effect relationships in psychopharmacology (see [Figure 6-1](#)). Specific pharmacogenomic data are discussed in detail elsewhere in this volume (see [Chapter 1, “Basic Principles of Molecular Biology and Genomics,”](#) by [Yu and Rasenick](#), as well as individual chapters on specific drugs or drug classes).

---

## Pharmacokinetics

---

The mathematical models and their accompanying differential equations that describe the time course of drugs and metabolites in the body were developed in the late 1960s and 1970s ([Gibaldi and Perrier 1975](#); [Wagner 1971](#)). These models were used to explain observational data as chromatographic techniques became available to measure nanogram quantities of drugs in animals and

humans. Unfortunately, the mathematical expertise required for development of these models makes them incomprehensible to most clinicians treating patients with drugs. The principles in this chapter have been validated with substantial experimental and observational data. However, these principles continue to be reexamined and refined. At the time pharmacokinetic models were first conceived, there was no knowledge of drug transporters. This rapidly evolving area of research is reshaping many of the tenets of drug disposition.

## Significance of Drug Transporters

Since the last update of this chapter, advances in the understanding of pharmacokinetics and pharmacodynamics of drugs have led to an investigative focus on the role of membrane-bound transporters in influencing drug distribution to various tissues ([Giacomini et al. 2010](#)). It is now recognized that multiple transporters present in the cerebral capillaries that form the blood-brain barrier (BBB) influence drug access to and accumulation in the central nervous system (CNS). Initial studies focused on the *ABCB1* gene product P-glycoprotein (P-gp) and revealed a role for this protein in altering the efflux of its substrates through the gastrointestinal tract, the BBB, and the placenta and in influencing drug elimination through the biliary tract and renal tubules. The amount of drug in various tissues correlated with the presence of transporters and their genetically determined activity. It soon became apparent that multiple transporters functioned at these sites, opposing each other in direction of transport and having overlapping substrate specificity. This complexity became

problematic for discerning the role of any single transporter in regulating CNS drug concentration. Much as with the genes that influence disease expression, it is unlikely that any single transporter polymorphism will be identified that could serve as a biomarker for pharmacokinetic/pharmacodynamic predictability. Other transporters in the brain capillary endothelial cells contributing to the function of the BBB include the uptake transporters organic anion transporting polypeptides 1A2 and 2B1 (OATP1A2, OATP2B1) and the efflux pumps P-gp, breast cancer resistance protein (BCRP), and multidrug resistance proteins 4 and 5 (MRP4, MRP5) ([Nigam 2015](#)).

Some provocative results have stimulated this field of research. When P-gp activity was lowered through use of a specific inhibitor, risperidone was found to have an increased drug concentration in the brain of rats that correlated with enhanced pharmacological effects that were surrogates for antipsychotic activity ([Pacchioni et al. 2010](#)). The translational application of this research is the possibility that use of specific inhibitors might increase CNS drug concentration and enhance central effects without causing an increase in peripheral drug concentration that relates to the development of adverse effects. The research supporting these types of investigations is built on a foundation of basic pharmacokinetic principles. The fundamental description of drug disposition begins with studies of single drug doses.

## Single-Dose Drug Disposition

### Absorption

The route of administration is a major determinant of the onset and duration of a drug's pharmacological effects. Intravenous injection ensures that all of the administered drug is available to the circulation. The rate of drug injection or infusion can be used to control completely the rate of drug availability. However, few psychopharmacological drugs are administered intravenously. Intramuscular administration is commonly thought to produce a rapid onset of effect, but exceptions have been documented. For example, drug absorption by this route was found to be slow and erratic with chlordiazepoxide ([Greenblatt et al. 1974](#)). The recent availability of intramuscular forms of some atypical antipsychotics will be advantageous for treating psychotic states when rapid tranquilization is desired and oral administration is impractical. For drugs that are equally well absorbed by the intramuscular and oral routes of administration, the total systemic exposure as reflected by the AUC from the two routes should be similar, as should the elimination half-life. A major difference is that the rate of absorption from the intramuscular route may be more rapid. Most psychoactive drugs are highly lipophilic compounds, which are well absorbed when taken orally.

Drug absorption is usually a passive process occurring in the small intestine. The efficiency of oral absorption is influenced by the physiological state of the patient, by formulation factors, and by the timing of administration around meals. Most drugs are best absorbed on an empty stomach. The presence of food or antacids in the stomach usually decreases the rate of drug absorption. Consistency in drug availability to the systemic circulation from oral absorption is promoted by administering each drug dose at a similar time in relation to meals. Normally, the presence

of food can be expected to reduce the peak drug concentration achieved in blood or plasma and to prolong the time required following an oral dose to reach the maximum plasma concentration. The absolute amount of drug absorbed may or may not be affected. Acute drug effects are facilitated by administration apart from meals. Sedative-hypnotic drugs are examples of drugs for which the rate of absorption is clinically meaningful ([Greenblatt et al. 1978](#)). Zolpidem's effectiveness in reducing the time to onset of sleep is considerably reduced if the drug is taken at bedtime in close proximity to food.

In recent years, the use of alternative routes of administration has increased. Buccal, sublingual, and transdermal routes of administration have the advantage of avoiding presystemic elimination, as absorption directly into the circulation avoids an initial pass through the liver before some drug is distributed to tissues. Hepatic elimination is dependent on the amount of drug extracted from blood as drug enters the liver, a function that is independent of the route of administration. Thus, the terminal elimination phase reflected by elimination half-life should not differ from one route of administration to another.

Formulation factors are especially meaningful when a drug effect is associated with achieving a minimal effective concentration (MEC) in plasma. [Figure 6-2](#) shows the predicted plasma concentration-time curves of a drug following a rapid intravenous injection (I), an oral formulation that is completely absorbed with no presystemic elimination (II), an incompletely absorbed oral formulation (III), and an extended-release formulation that results in slow absorption of drug (IV). A formulation with poor bioavailability (III) may never achieve a plasma

concentration above the MEC, whereas a drug whose absorption is delayed (IV) may retard the onset of effect but maintain an effective concentration for a period similar to that for the more rapidly available formulations (I, II). The principle of an MEC may apply in antipsychotic therapy, where minimal occupancy of dopamine  $D_2$  or other receptors during a dosage interval may be needed for optimal therapeutic benefit.

**FIGURE 6-2.** Predicted plasma concentration curves following single doses of a drug by rapid intravenous injection (I), a dosage form with complete bioavailability (II), a dosage form with reduced bioavailability (III), and an extended-release dosage

form that reduces the rate but not the completeness of absorption (IV).

MEC=minimal effective concentration.

Research in pharmaceutical science continues to produce new systems for controlling the release of oral drugs. These include coated systems, with a core of active drug surrounded by a slow-releasing film, and matrix systems, with active drug distributed in erodible gel matrices, and other hydrophilic, swellable, or erodible polymers, to slowly dissolve and release the drug at predictable rates to produce one or more peak concentrations during a dosage interval. Bupropion, paroxetine, venlafaxine, and the psychostimulants used to treat attention-deficit/hyperactivity disorder (ADHD) are examples of drugs whose clinical utility has been improved by reformulation as controlled-release dosage forms. Recently, a controlled-release oral suspension was developed for delivery of methylphenidate. Among the immediate-release dosage formulations, a general rank order of products providing the most rapid to the slowest rate of drug release for oral absorption is solutions, suspensions, tablets, enteric- or film-coated tablets, and capsules. Regardless of the dosage formulation selected, the last several hours of declining drug concentration in plasma occur in parallel, because the drug's rate of elimination is unaffected by its rate or extent of absorption (see [Figure 6-2](#)). The time at which a terminal elimination phase is clearly observable following a single dose may be delayed, but the terminal elimination half-life is unchanged. Formulation as controlled-release tablets or capsules may allow drugs with short elimination half-lives, which must be given multiple times per day to maintain an

effective concentration, to be effective when administered only once or twice daily.

## Presystemic Elimination

Many drugs undergo extensive metabolism as they move from the gastrointestinal tract to the systemic circulation (i.e., as they pass through the gastrointestinal membranes and hepatic circulation during absorption). This process is known as the *first-pass effect* or *presystemic elimination* and is an important determinant of drug bioavailability after oral administration. Several factors are potentially important in influencing the degree of first-pass effect. Food has been mentioned previously as one factor. A first-pass effect is usually indicated by either a decreased amount of parent drug reaching the systemic circulation or an increased quantity of metabolites after oral administration compared with parenteral dosing. This process is important in the formation of active metabolites for psychoactive drugs and is a major source of pharmacokinetic variability ([George et al. 1982](#)).

Presystemic metabolism of drugs is extensively accomplished by cytochrome P450 (CYP) enzymes located both in the liver and in the luminal epithelium of the small intestine ([Kolars et al. 1992](#)). CYP3A4 represents approximately 70% of total CYP in the human intestine. Many useful psychopharmacological drugs are CYP3A4 substrates, inhibitors, and/or inducers. The liver contains about two- to fivefold greater amounts of CYP3A protein (nmol/mg protein) compared with the intestine ([de Waziers et al. 1990](#)). Nevertheless, intestinal CYP3A4 has a profound effect on presystemic drug metabolism. Up to 43% of orally administered midazolam, for example, is metabolized as it passes through the intestinal mucosa

([Paine et al. 1996](#)). The exposure of drugs to gut CYP3A4 is not limited by binding to plasma proteins, as can occur with hepatic metabolism. Slower blood flow may also contribute to intestinal metabolism, thereby compensating for the lower quantity of CYP3A4 in the gut compared with the liver.

Certain foods, such as grapefruit juice, can substantially alter the bioavailability of some drugs. Components in grapefruit juice—which contains a variety of suspect candidates, including naringin, other flavonoids, bergamottin, and other furanocoumarins—inhibit intestinal CYP3A4-mediated first-pass metabolism ([Paine et al. 2005](#)). The maximal effect can occur within 30 minutes of ingestion of juice. Grapefruit juice may also inhibit the efflux transport of drugs by P-gp and MRP2. In the gut, P-gp works in concert with CYP3A4 to limit the intestinal absorption of drugs that are common substrates for both proteins. Efflux transporters minimize drug absorption by recycling drug that has escaped metabolism back to the gastrointestinal tract for further exposure to enzymatic elimination before absorption. Current research aims to develop nonabsorbable inhibitors of drug transporters to increase drug bioavailability. Such compounds would be useful for coadministration with drugs having poor bioavailability or excessive costs.

Changing the route of administration to avoid presystemic metabolism can have a therapeutic advantage. When given orally, selegiline, an irreversible inhibitor of monoamine oxidase (MAO), is substantially converted to several metabolites through extensive first-pass metabolism. Transdermal dosing with drug contained in a removable patch adhering to the skin results in higher systemic exposure to selegiline and lower exposure to

metabolites. This allows greater CNS exposure to selegiline from a given dose to inhibit MAO relative to the required dose from oral administration ([Azzaro et al. 2007](#)).

In summary, an important pharmacokinetic principle is that the choice of drug formulation and the route of administration can determine the rate at which the drug and metabolites appear in the systemic circulation. This rate may be manipulated to retard the magnitude of the peak plasma drug concentration when a high peak concentration is related to the occurrence of adverse effects. For example, slow-release formulations of lithium and paroxetine reduce gastrointestinal side effects ([DeVane 2003](#)). Alternatively, rapid absorption may be desirable to achieve immediate pharmacological effects.

## **Distribution**

Drug distribution to tissues begins almost simultaneously with absorption into the systemic circulation. The rate at which distribution occurs will partially influence the onset of pharmacological response. Access to effect sites depends on membrane permeability, the patient's state of hydration, regional blood flow, and other physiological variables. Physicochemical properties influencing the rate of drug distribution to effect sites include lipid solubility, ionizability, and affinity for plasma proteins and tissue components. Diazepam is highly lipophilic, and its onset of effect is rapid as a result of its entry into the brain within minutes after oral administration ([Greenblatt et al. 1980](#)). The concentration of diazepam at its effect site may fall so precipitously as a result of redistribution that diazepam's duration of action after an initial dose is shorter than would be expected based on its elimination half-life.

Frequently, the intensity and duration of the pharmacological effect of a second drug dose, taken immediately after cessation of the effect of the first dose, are greater and longer, respectively, than the intensity and duration of the effect of the first dose. This is known as the *second-dose effect* in pharmacokinetics (DeVane and Liston 2001). When dosing is repeated before the previous dose has been eliminated from the body, the second and subsequent doses produce a greater effect than the initial dose, but the relative intensity of subsequent doses diminishes. This second-dose effect occurs, regardless of the half-life of the drug, when dosing is repeated in response to the observed effect. Common examples of this phenomenon include the self-administration of caffeine and the administration of certain anesthetics.

The predicted time course of drug concentration in plasma and in tissue following a single intravenous drug injection is shown in Figure 6-3. Drug concentration in plasma rapidly declines in a manner consistent with the extensive distribution of the compound out of the systemic circulation. Drug concentration in tissue rapidly increases during this time. Pharmacological effects may not occur immediately but may be delayed until the tissue concentration at the effect site rises above an MEC. An equilibrium eventually occurs between drug in plasma and drug in tissue. Concentrations from this time forth decline in parallel during a terminal elimination phase.

**FIGURE 6-3.** Predicted concentration of a drug in plasma and tissue following a rapid intravenous injection.

MEC=minimal effective concentration.

The observed time course of drug concentration changes in plasma has frequently been considered in the pharmacokinetic literature to confer the characteristics on the body of a two-compartment mathematical model (Gibaldi and Perrier 1975). Physiological systems are so complex that a complete mathematical model of drug transit through the body cannot be achieved. Therefore, it is necessary to reduce a mathematical description of the real system with a series of simplifying assumptions regarding drug behavior in the body. Many drugs appear to

be first absorbed into a central compartment (composed of the circulation and rapidly equilibrating tissues) and then distributed to less accessible tissues (which collectively form a peripheral compartment). This compartmentalization of drug concentration greatly aids mathematical analysis of pharmacokinetic data.

Even though the drug concentration can vary widely among tissues, equilibrium eventually occurs between drug concentration in plasma and in tissue (see [Figure 6-3](#)). The concentration of drug in brain tissue may be substantially different—higher or lower—from that in plasma, but reduction of the plasma drug concentration through renal and hepatic elimination of drug from the central compartment should be mirrored by a proportional reduction of drug concentration from the brain or other tissues. For this reason, an MEC determined from plasma data may reflect an MEC at the effect site. The distribution of a drug in the body largely depends on the drug's relative binding affinity to plasma proteins and tissue components and the capacity of tissues for drug binding. This pharmacokinetic principle is illustrated in [Figure 6-4](#). Only unbound drug is capable of distributing between plasma and tissues. Different degrees of plasma protein binding among antidepressants, for example, cannot be used to draw valid conclusions about the availability of drug to exert pharmacological effects at the site of action ([DeVane 1994](#)). The nonspecific binding of drugs to tissue components complicates the interpretation of the significance of plasma protein-binding differences among drugs. Drug binding in tissues cannot be measured directly in vivo and must be inferred using mathematical models and/or in vitro methods.

**FIGURE 6-4.** Effect of protein binding on distribution of drug between plasma and tissue.

Most drugs circulate in the blood bound to plasma proteins, principally albumin or alpha-1-acid glycoprotein. Many psychotropic drugs are highly protein bound, frequently to a degree greater than 90%. Displacement of drug from plasma protein-binding sites may result from drug-drug interactions. This situation should lead to more unbound drug being available for distribution to peripheral tissues and interaction with receptor sites (see [Figure 6-4](#)). As a result, potentially greater pharmacological effects, either beneficial or detrimental, may be expected. However, there are few documented examples in which the above events occurred with psychoactive drugs and led to significant clinical consequences. Compensatory changes occur in the body to buffer the impact of drug-binding interactions ([DeVane 2002](#)). When plasma protein binding is restrictive regarding the drug's hepatic and/or renal elimination, the increased free drug concentration in plasma will be a transient effect as more free (non-protein-bound) drug becomes available to routes of elimination. Total (bound plus free) drug concentration in plasma will eventually return to a predisplacement value. The conclusion of several authoritative reviews is that plasma

protein-binding displacement interactions are rarely a major source of variability in psychopharmacology (DeVane 2002; Greenblatt et al. 1982; Rolan 1994; Sellers 1979).

## Elimination

Drugs are eliminated or cleared from the body through renal excretion in an unchanged or conjugated form; through biotransformation, primarily in the liver, to polar metabolites; or through both of these mechanisms (see Figure 6-1).

*Clearance* is defined as the volume of blood or other fluid from which drug is irreversibly removed per unit of time. Thus, clearance units are volume per time. Drug clearance is analogous to creatinine clearance by the kidney. From the blood that delivers drug to the liver, or any other eliminating organ, an extraction occurs as blood travels through the organ. Because drug extraction by the liver and other organs is rarely 100%, the portion that escapes presystemic elimination reaches the systemic circulation intact. Plasma protein binding, as mentioned above, can restrict the organ extraction process, depending on the specific drug. If a drug were to be completely extracted, then clearance would equal the blood flow to the organ. An average hepatic blood flow is 1,500 mL/minute. When drug is eliminated by additional organs, the total clearance is an additive function of all the individual organ clearances. Clearance values in excess of 1,500 mL/minute reported for many psychopharmacological drugs are reflective of presystemic elimination (DeVane 1994). When the drug dose and bioavailability are constant, then clearance is the pharmacokinetic parameter that determines the extent of drug accumulation in the body to a steady state. By

contrast, elimination half-life is useful to reflect the rate, but not the extent, of drug accumulation.

*Elimination half-life* is defined as the time required for the amount of drug in the body, or drug concentration, to decline by 50%. This parameter is commonly determined after a single-dose pharmacokinetic study or after drug discontinuation in a multiple-dose study. In either situation, drug concentration decline in plasma can be followed by multiple (serial) blood sampling. Half-life is easily determined by graphical means or by inspection, as long as data are used from the terminal log-linear portion of the elimination curve (see [Figures 6-2](#) and [6-3](#)). Knowledge of a drug's elimination half-life is particularly useful for designing multiple-dosing regimens.

## Multiple Dosing to Steady State

Multiple drug doses usually are required in the pharmacotherapy of mental illness. During a multiple-dosing regimen, second and subsequent drug doses are usually administered before sufficient time has elapsed for the initial dose to be completely eliminated from the body. This process results in drug accumulation, as illustrated in [Figure 6-5](#). When drug elimination follows a linear or first-order process, the amount of drug eliminated over time is proportional to the amount of drug available for elimination ([Gibaldi and Perrier 1975](#)). Accumulation does not occur indefinitely; rather, it reaches a steady state. A *steady state* exists when the amount of drug entering the body is equal to the amount leaving the body. From a practical standpoint, this definition means that after a period of continuous dosing, the body retains a pool of drug

molecules from several doses, and the drug eliminated each day is replaced by an equivalent amount of newly administered drug. The time required from the first administered dose to the point at which an approximate steady state occurs is equivalent to the total of four to five elimination half-lives. The same amount of time is required for a new steady state to be achieved after an increase or decrease in the daily dosing rate or for a drug to wash out of the body after dosing is discontinued (see [Figure 6-5](#)).

**FIGURE 6-5.** Accumulation of drug during multiple dosing.

It takes four to five half-lives ( $4-5 t_{1/2}$ ) to achieve initial steady state ( $C_{pss}$ ) on a constant dosage regimen, to achieve a new steady state after an increase in dosage, or to wash out drug from the body after

discontinuation. The average steady-state concentration lies somewhere between the peaks and troughs of drug concentration during a dosage interval.

The term *steady state* is a misnomer in that a true drug steady state occurs only with a constant-rate intravenous infusion. Because of the concurrent processes of drug absorption, distribution, and elimination, drug concentration is constantly changing in plasma and tissues during an oral dosing regimen. A peak and a trough concentration occur within each dosage interval. The average steady-state concentration occurs somewhere between these extremes and is determined by the daily dosage and the drug's total body clearance for that individual.

On reaching a steady-state concentration, the average concentration and the magnitude of the peaks and troughs may be manipulated according to established pharmacokinetic principles. [Figure 6-6](#) shows the predicted plasma concentration changes based on drug doses given every 24 hours. The selected dose does not produce a high enough average steady-state concentration to reach the desired concentration range between an MEC and a concentration threshold associated with an increased risk of toxicity. When the dose is doubled and the dosage interval is kept constant, the average steady-state concentration increases, but the magnitude of the peak and trough concentration difference also increases. These changes are consistent with the pharmacokinetic principles of superposition and linearity ([Gibaldi and Perrier 1975](#)).

**FIGURE 6-6.** Predicted plasma concentration changes from administering either a selected dose (D) every 24 hours (D q24h), twice the dose every 24 hours (2D q24h), or the original dose every 12 hours (D q12h).

MEC=minimal effective concentration.

*Linearity* refers to maintaining a stable clearance across the usual dosage range. Within the linear dose range, the magnitude of a dosage increase results in a proportional change in steady-state concentration (see [Figure 6-6](#)). The magnitude of the dose change theoretically superimposes on the new peak and trough concentration. In [Figure 6-6](#), doubling the daily dose results in an adequate average steady-state concentration, but the new peak and trough concentration values cause both an increased risk of

toxicity and an inadequate concentration, with plasma levels declining below the MEC for a portion of each dosage interval. An alternative is to increase the total daily dose and divide it into more frequent administrations. This is accomplished by administering the original dose every 12 hours instead of every 24 hours. The new average steady-state concentration remains within the desired range, and the differences between the peak and trough concentrations are reduced to an acceptable fluctuation.

Selection of a proper drug dosage regimen must consider both the amount of drug administered and the frequency of administration. Some drugs with half-lives long enough to be administered once daily may not be suitable for administration every 24 hours because toxicity may be precipitated by an excessive peak concentration from a single dose. Examples include lithium and clozapine. Once-daily dosing with lithium may produce gastrointestinal intolerance, and clozapine is dosed two or more times each day to avoid peak concentrations that might predispose to seizure activity. Bupropion was initially formulated to be dosed multiple times a day to avoid high peak concentrations in plasma for this same reason, but its reformulation as an extended-release tablet allowed for once-daily administration. When high peak concentration is tolerable, the dosage interval can theoretically be extended beyond 1 day by use of larger amounts of drug in single doses taken less frequently. This principle applies to fluoxetine, which is available as a 90-mg capsule for once-weekly administration. Drugs with elimination half-lives much longer than 24 hours, such as aripiprazole, could theoretically be administered once every several days to maintain adequate drug in the body for therapeutic effects. However, combining the dose for several days into a single

administration may increase the risk of adverse events. The development of long-acting intramuscular formulations of atypical antipsychotic drugs—such as those for risperidone or aripiprazole, which can be administered as infrequently as biweekly or monthly, respectively—offers the advantage of transparency of medication adherence.

## Pharmacodynamics

---

Pharmacodynamic variability may exceed pharmacokinetic variability (see [Figure 6-1](#)). The drug dosage or concentration that produces a pharmacological effect differs widely among patients. Similarly, pharmacological effects can vary widely among patients with comparable plasma concentrations of drug.

The principles of dosage regimen design discussed above rely heavily on the existence of a functional relationship between the concentration at an effect site and the intensity of the response produced. Many observed processes in nature behave according to the sigmoid relationship shown in [Figure 6-7](#). At a low dosage or concentration, only a marginal effect is produced. As drug dosage or concentration increases, the intensity of effect ( $E$ ) increases until a maximum effect ( $E_{\max}$ ) is achieved. This response is observed as a plateau in the sigmoid dose-effect curve (see [Figure 6-7](#)). Further dosage increases do not produce a greater effect.

**FIGURE 6-7.** The sigmoid maximum effect ( $E_{\max}$ ) pharmacodynamic model relates concentration ( $C$ ) to intensity of effect ( $E$ ).

$EC_{50}$  is the concentration that produces half of the  $E_{\max}$ , and  $n$  is an exponent that relates to the shape of the curve.

The dose-effect relationship in [Figure 6-7](#) has practical applications to psychopharmacology. The increase in drug response that results from an increase in dosage depends on the shape and steepness of the theoretical dose-response curve for each patient and the starting point on the curve when a dosage is changed. At low dosages or concentrations, a substantial dose increase may be necessary to achieve an effect. In a linear part of the relationship, dosage increases should result in proportional

increases in effect. In the higher dosage or concentration range, a further increase will not produce a significant increase in effect because of diminishing returns. This phenomenon is likely caused by the saturation of molecular targets by drug molecules above a critical concentration.

Drugs rarely have a single pharmacological effect or interact with only a single receptor population or molecular target. Drugs generally have affinity for multiple receptors; therefore, several theoretical concentration-effect relationships can exist for a given drug. Dose-response curves are shown in [Figure 6-8](#) for a drug that produces a therapeutic effect and mild and severe toxicity. The greater the separation between the curves for therapeutic and toxic effects, the more safely the drug can be administered in increasing doses to achieve therapeutic goals. Estimates of these interrelationships are made in preclinical animal studies and Phase I human studies for drugs in development. In clinical practice, the degree of separation between these curves and their steepness will show both inter- and intraindividual variability. Concurrent medical illness may predispose patients to side effects by effectively causing a shift to the left in one or both of the concentration-toxicity curves. This narrows the range over which doses can be safely administered without incurring adverse effects. The  $EC_{50}$  in [Figure 6-8](#) produces negligible toxicity. Increasing the concentration with a dosage increase to gain an increased response can only be accomplished at the expense of mild toxicity. As the dosage and concentration increase, therapeutic effects approach a plateau, and small increments in concentration result in a disproportionate change in toxicity.

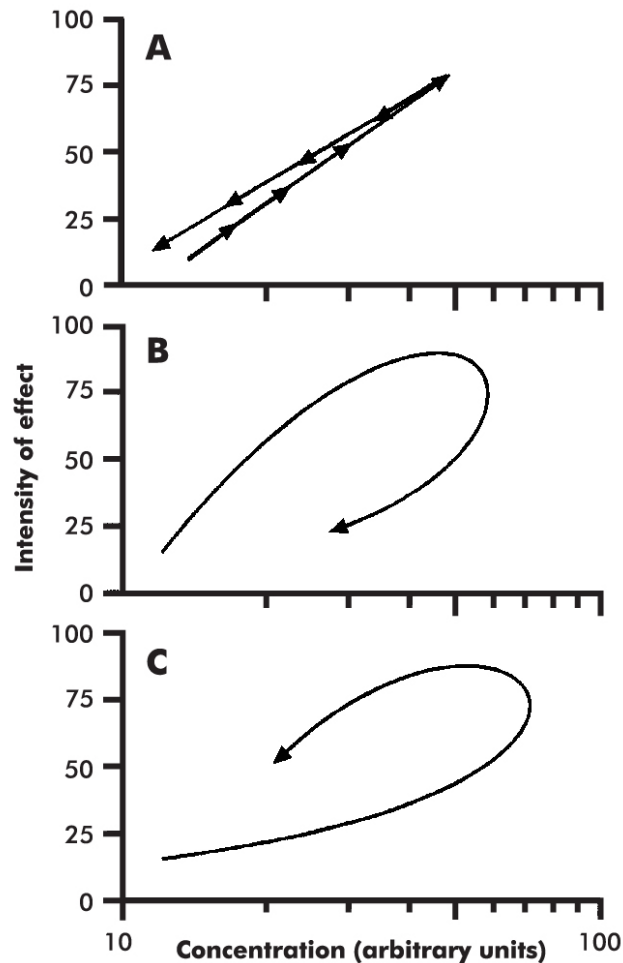

**FIGURE 6-8.** Concentration–effect curves for a drug that produces a therapeutic effect and mild (A) and severe (B) toxicity.

The concentration is shown for a therapeutic effect that produces 50% of the maximum effect ( $EC_{50}$ ).

The pharmacodynamic relationships considered above are most reproducible when pharmacological effects are direct and closely related to plasma concentration. In [Figure 6-9](#), the concentration–effect relationship is shown as a function of drug concentration changes over time. In [Figure 6-9A](#), the changes in effect are almost superimposable with the increase and decrease in concentration. This type of relationship often reflects a direct action of the drug with a single receptor. This

straightforward relationship is generally not observed in psychopharmacology.

**FIGURE 6-9.** Theoretical relationships of drug concentration versus intensity of effect.

Drug concentration changes occur in the direction of the arrow. Effects superimposable on concentration changes **(A)** suggest a direct and reversible interaction between drug and receptor, a clockwise hysteresis curve **(B)** suggests the development of

tolerance, and a counterclockwise curve **(C)** suggests an indirect effect or the presence of an active metabolite.

In [Figure 6-9B](#), the response has begun to diminish with time before concentration begins to decline. This type of plot is known as a *clockwise hysteresis curve*. The observed effect may be explained by the development of tolerance. The time course of tolerance to psychoactive drug effects varies from minutes to weeks. Acute tolerance to some euphoric effects of cocaine can occur following a single dose ([Foltin and Fischman 1991](#)). Tolerance to the sedative effects of various drugs may take weeks. The mechanisms operative in the development of tolerance include acute depletion of a neurotransmitter or cofactor, homeostatic changes in receptor sensitivity from blockade of various transporters, and receptor agonist or antagonist effects. Ultimately, cellular responses to chronic treatment with drugs can alter gene transcription factors as mediators of physical and psychological aspects of tolerance ([Nestler 1993](#)).

A time delay in response occurs when effects are increasing and are maintained despite decreasing plasma drug concentration (see [Figure 6-9C](#)). This results in a *counterclockwise hysteresis curve*. A pharmacokinetic explanation of this lag in response may involve a delay in reaching the critical drug MEC at the effect site until the plasma concentration has already begun to decline. Alternatively, response may depend on multiple “downstream” receptor effects. Response may increase despite a decreasing drug concentration when a metabolite contributes to the observed effects. To overcome these complications, kinetic dynamic models can incorporate an “effect” compartment (see [Figure 6-1](#)). The effect site

equilibrates with plasma after a finite time, which can be assigned a half-life.

## **Variability in the Dose-Effect Relationship**

---

A major challenge of treating mental illness with drugs is that both pharmacokinetic and pharmacodynamic variability complicate the dose-effect relationship. The presence of active metabolites, the influence of pharmacogenomics, and the effects of combining two or more drugs contribute to variability. Nonadherence to the prescribed treatment plan on the part of the patient can seriously undermine reliability in the expected effects from pharmacotherapy. Differences in sex, age, and weight and the presence of hepatic or other disease states are major factors that increase the need for individualization of therapy.

### **Active Metabolites**

With the exceptions of lithium and gabapentin, which are renally excreted, drugs used in clinical psychopharmacology are cleared partially or completely by metabolism, primarily in the liver. A general characteristic of highly lipid-soluble drugs is a likelihood of elimination involving metabolism, whereas water-soluble drugs will undergo some degree of clearance from the body by renal elimination in an unchanged form. Many psychoactive drugs produce pharmacologically active metabolites that

distribute to the effect sites (see [Figure 6-1](#)). Like their precursors, metabolites may have multiple pharmacological effects that may be similar to or different from those of the parent drug.

When pharmacotherapy is being switched from one drug or drug class to another, the presence of any active metabolites should be considered. Norfluoxetine, for example, has an average half-life of 8-9 days, much longer than the average of 2-3 days for fluoxetine, its parent drug ([DeVane 1994](#)), and it is an equipotent serotonin reuptake inhibitor. It may take several weeks for this metabolite to clear the body after discontinuation of fluoxetine ([Pato et al. 1991](#)). A similar situation applies to aripiprazole and its active metabolite dehydroaripiprazole, which have elimination half-lives approaching 75 hours and 94 hours, respectively.

Metabolites will accumulate to a steady state in the body in relation to their own elimination half-lives and not those of their parent drugs. For a drug that is nearly completely metabolized in the liver, a characteristic of numerous psychoactive drugs, the metabolites will always have an elimination half-life that is equal to or longer than the half-life of the parent drug. This is a logical conclusion of considering that a metabolite cannot be eliminated faster than it is formed. Of course, administration of the metabolite as a separate molecular entity apart from the parent drug would produce a drug concentration-time curve independent of any influence of the metabolite being formed from a precursor in vivo. For some drugs, the full expression of direct pharmacological effects may not be expected until both the drug and any important active metabolites have all attained their steady-state concentration. For drugs producing indirect effects, when

the response depends on second messengers or a cascade of receptor actions, the waiting period for fully expressed effects may be even longer.

---

## Stereochemistry

---

Stereochemistry or chirality of drug molecules is an important consideration in pharmacokinetics. Many psychoactive drugs exist as two or more stereoisomers or enantiomers with distinctly different biological properties and are marketed as the racemic (i.e., 50:50) mixtures of both isomers. Although enantiomers have identical physicochemical properties, they are often recognized as distinct entities by biological systems and may bind to transport proteins, drug-metabolizing enzymes, and pharmacological effect sites with different affinities. As a result, one enantiomer may possess a significant pharmacological effect, whereas the other stereoisomer may lack that effect or produce different effects. Enantiomers may also differ in their absorption, metabolism, protein binding, and excretion, leading to substantial differences in pharmacokinetic properties ([Darwish et al. 2009](#); [DeVane and Boulton 2002](#)). Furthermore, one isomer may modify the effects of the other. Motivation for development of individual enantiomers has been stimulated by reports that some enantiomers may antagonize or counteract the activity of the other stereoisomer.

The development of single-isomer drugs may offer advantages over use of the racemic mixture. Potential advantages include a less complex and more selective

pharmacological profile, a possibly improved therapeutic index, a more simplified pharmacokinetic profile, a reduced propensity for complex drug interactions, and a more definable relationship between plasma drug concentration and effect. Examples of racemic mixtures in current use include methadone, methylphenidate, bupropion, venlafaxine, fluoxetine, and citalopram. Clearly, each drug needs to be considered individually with regard to its development as a single stereoisomer formulation. Recent examples of successful switches to single isomers include escitalopram, dexamethylphenidate, and armodafinil.

## Pharmacogenomics

---

Inheritance accounts for a large part of the variations observed in the ability to eliminate drugs (see [Figure 6-1](#)) among individuals. This forms the basis of *pharmacogenetics*, which is defined as the study of the genetic contribution to the variability in drug response ([Kalow et al. 1986](#); [Price Evans 1993](#)). This term was originally applied to the effect on pharmacokinetics, whereas *pharmacogenomics* dealt specifically with genes mediating drug response. More recently, the terms have been used interchangeably. Numerous association studies have investigated genetic polymorphisms of molecular targets as predictors of disease susceptibility, specific drug response, and drug tolerability. Recent pharmacogenomic studies have yielded advances in five areas: 1) the role of serotonin pharmacogenomic targets in predicting response to antidepressants ([Lekman et al. 2008](#); [Liu et al. 2007](#); [Serretti et al. 2007](#); [Yatham et al. 1999](#)); 2) the role of

potential pharmacogenomic targets in predicting response to prophylactic lithium in bipolar disorder (Masui et al. 2006; Serrenti et al. 2002); 3) the relationship between polymorphisms in serotonin, dopamine, and glutamate receptor genes and antipsychotic response in schizophrenia (Arranz et al. 1998; Bishop et al. 2005); 4) the relationship between the pharmacogenomics of the  $\mu$ -opioid receptor and treatment response to naltrexone in alcohol use disorder (Oslin et al. 2003); and 5) the role of pharmacogenomics in the occurrence of adverse effects from psychopharmacotherapy (Murphy et al. 2003, 2004). Specific pharmacogenomic data are discussed elsewhere in this volume (see Chapter 1, “Basic Principles of Molecular Biology and Genomics,” by Yu and Rasenick).

The genetic differences in pharmacokinetics that have been identified apply mostly to drug metabolism. Renal clearance of drugs appears to be similar in age- and weight-matched healthy subjects with no defined genetic polymorphisms. Genetic polymorphisms have been identified and defined for some drug transporters and several hepatic enzymes important in the cellular transport and metabolism of many drugs used in psychopharmacology.

P-gp, as the most thoroughly studied drug transporter, appears to be significantly involved in the disposition of a variety of psychoactive drugs (Mahar Doan et al. 2002). More than 70 polymorphisms have been reported in the *ABCB1* gene that encodes for P-gp, and three single-nucleotide polymorphisms (SNPs) of P-gp have been associated with functional changes in P-gp activity. The majority of SNP-related reports focus on the silent C3435T SNP of exon 26, which has been associated with changes in expression resulting in increased serum concentrations of

digoxin and fexofenadine ([Hoffmeyer et al. 2000](#); [Kurata et al. 2002](#)). There is emerging evidence that haplotypes of P-gp SNPs may influence drug-resistant epilepsy ([Siddiqui et al. 2003](#)), access of drugs to the brain ([Brunner et al. 2005](#)), and placental transfer of psychoactive drugs ([Rahi et al. 2007](#)). Theoretically, P-gp substrates may act as competitive inhibitors of P-gp, so that drug-drug interactions may also involve P-gp ([Wang et al. 2006](#)).

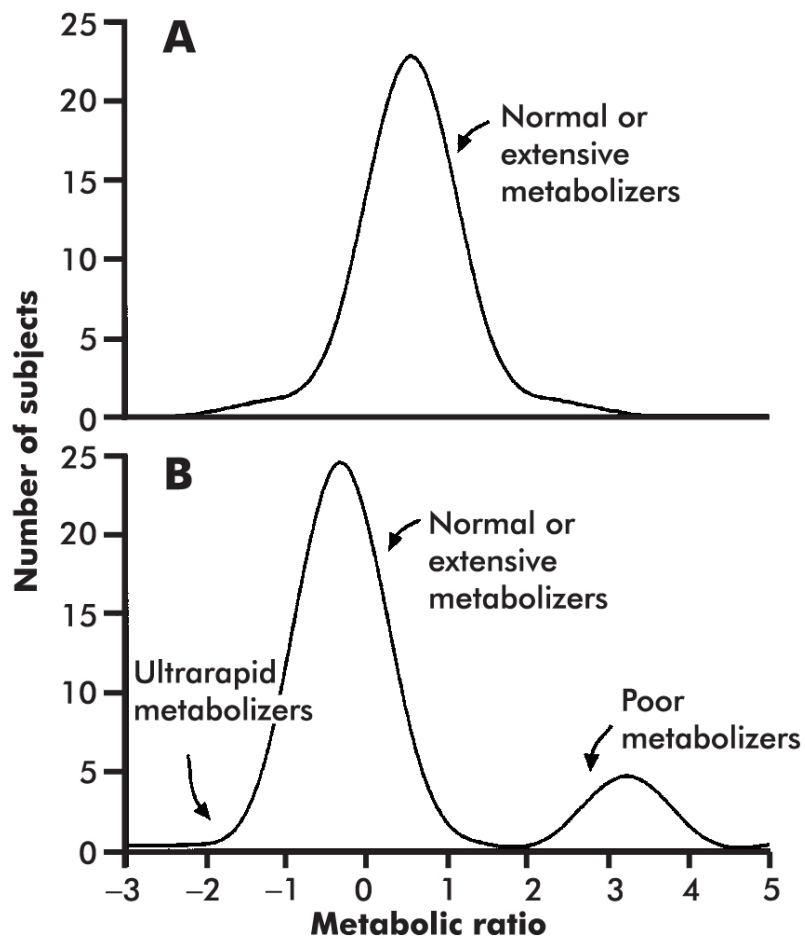

Basic research describing the functional capacity of P-gp to influence the distribution of drug substrates in several tissues, including access to the brain, has led to translational studies that demonstrated *ABCB1* genetic effects on antidepressant outcomes. In 297 depressed patients treated for 6 weeks with antidepressants, several *ABCB1* polymorphisms from 95 genotyped SNPs were associated with remission. A relationship between genotype and remission was found in patients receiving antidepressants that were P-gp substrates but not in patients receiving non-P-gp substrates ([Uhr et al. 2008](#)). This seminal observation led to a prospective study in which *ABCB1* gene test results from 58 depressed inpatients were incorporated into the clinical decision-making process ([Breitenstein et al. 2014](#)). Either increasing the drug dosage or switching to another antidepressant when patient-specific genotyping was available resulted in higher remission rates in patients whose *ABCB1* genotype was available during the hospital stay. The largest trial to date to test the value of *ABCB1* genotyping was performed as part of the prospective multicenter iSPOT antidepressant trial ([Schatzberg et al. 2015](#)). In this intent-to-treat sample of 683 depressed patients, a specific variant, rs10245483, was found to be closely correlated with medication-specific antidepressant efficacy and adverse events. Considered

together, this research affirms that drug transporters influence pharmacodynamic effects by active transport to sites containing molecular targets. Further research will define the principal polymorphisms of value for therapeutic decision making.

Genetic polymorphism in a drug-metabolizing enzyme or transporter can result in subpopulations of people who may deviate substantially from the population mean in their ability to metabolize substrates of the affected enzyme. People who are poor metabolizers constitute at least 1% of the population, but the majority of people are normal or rapid metabolizers, and some are identified as ultrarapid metabolizers due to duplicate or multiple genes. Genetic polymorphisms that define poor metabolizers have been identified for major drug-metabolizing enzymes, including CYP2D6, CYP2C9, and CYP2C19. Studies employing either single drugs or mixtures of drugs as probe compounds have been used to calculate an individual's metabolic ratio (MR)—an index of relative ability to metabolize substrates of a particular enzyme—thereby providing a phenotype identity. The MR is equal to the concentration of parent drug divided by the concentration of the major metabolite determined in the urine excreted during a timed interval following an oral dose.

Many pharmacogenetic studies yield results similar to the frequency distribution histograms shown in [Figure 6-10](#). The frequency in [Figure 6-10A](#) is expected when enzyme activity is distributed normally within a population without genetic polymorphisms. The range of values for the MR may be broad, which reflects a large variability in oxidation reaction capacity in the study population. Thus, vastly different dosages are required for many patients. The bimodal distribution in [Figure 6-10B](#) is a typical finding for

an enzyme that has a genetic polymorphism. Values above the antinode for the reference (or “probe”) drug define poor metabolizers, who are clearly differentiated from normal or extensive metabolizers. The probe drug need not be metabolized by only one enzyme (as is exemplified by the use of caffeine for phenotyping the enzyme activity of *N*-acetyltransferase and CYP1A2), but the overlap of other enzymes should be minimal in order to produce the specific metabolite of interest ([Denaro et al. 1996](#)). Comparisons of MRs across many patients of different ethnic origins have yielded measures of variability in enzyme activity in the population ([Lin et al. 1996](#)). The widespread availability of a commercial microarray chip for genotyping a small group of CYP enzymes has eliminated the need to perform phenotyping procedures in most circumstances. Although a genotypical extensive metabolizer may be phenotypically a poor metabolizer, the opposite situation does not occur.

**FIGURE 6-10.** Theoretical frequency histograms of the distribution of the metabolic ratio of a model substrate showing a unimodal distribution among a population of normal or extensive metabolizers **(A)** and a bimodal distribution among a population including poor metabolizers and ultrarapid metabolizers **(B)**.

The potential clinical consequences of being a poor metabolizer will vary according to the activity of the administered drug and any active metabolites. When the

drug is active and a pathway is affected (a situation that usually produces an inactive metabolite), higher drug concentrations can be expected. This result can lead to an exaggerated response and potential toxicity. The most serious consequences would be expected from drugs with a narrow therapeutic window. For example, when perphenazine (a drug with a narrow therapeutic window) was given to elderly patients who were poor metabolizers of CYP2D6, extrapyramidal side effects were exaggerated ([Pollock et al. 1995](#)). If the therapeutic effects depend on the formation of an active metabolite, diminished response can be expected from a lower concentration of metabolite in poor metabolizers. For example, normal doses of codeine, which is partially metabolized to the more potent morphine, may provide an inadequate analgesic effect.

For CYP2D6, the poor-metabolizer status is inherited as an autosomal recessive trait. At least 70 different alleles have been defined for the CYP2D6 gene, and many types of null mutations result in impaired CYP2D6 activity ([Gonzalez and Idle 1994](#)). Several techniques available in the field of molecular biology have a high sensitivity for detecting the mutant alleles and can establish a genotype. This procedure can be beneficial in drug development to profile test compounds for affinity to enzymes and transporters and in some forensic circumstances to help establish the cause of excessive drug concentrations. Genetic phenotyping is potentially more clinically useful than genotyping and can be done when patients are drug free to characterize their relative ability to metabolize drug substrates. About 1% of Caucasians are ultrarapid metabolizers because of an amplification of the functional CYP2D6 gene ([Johansson et al. 1993](#)). These patients have the lowest MR when phenotyped with a CYP2D6 substrate with a high urinary

concentration of metabolite and a low parent drug concentration (see [Figure 6-10B](#)). The implication is that these individuals will often require very high dosages of drugs that are CYP2D6 substrates. Research is needed to support phenotyping and genotyping as an aid in the initial selection of drugs and drug dosages for promoting precision medicine.

Of the human CYP enzymes, three families (CYP1, CYP2, and CYP3) are involved in drug metabolism ([Guengerich 1992](#); [Wrighton and Stevens 1992](#)). The enzymes most relevant to psychopharmacology are CYP enzymes 1A2, 2A6, 2B6, 2C9, 2C19, 2D6, 2E1, and 3A4. Interindividual differences in the expression and catalytic activities of CYP result in a large variation in the in vivo metabolism of drugs. Average immunoquantified levels of the various specific CYP enzymes in 60 human liver microsomal samples were reported by [Shimada et al. \(1994\)](#). [Benet et al. \(1996\)](#) and [Wrighton and Stevens \(1992\)](#) estimated the participation of the liver CYP enzymes in drug metabolism based on known substrates and pathways. These values are compared in [Table 6-1](#). Among the CYP enzymes in the liver, CYP3A is present in the largest amounts and participates in the metabolism of the greatest number of drugs. Together, CYP3A and CYP2D6 participate in the metabolism of an estimated 80% of currently used drugs.

In summary, recent pharmacogenetic investigations have yielded fruitful data relating to the causes of pharmacokinetic variability in the dose-effect relationship. The polymorphism of molecular drug targets in the brain is a source of pharmacodynamic variability. Pharmacogenetic studies have extensively used metabolic phenotyping with model substrates for specific enzymes to characterize several genetic polymorphisms. The practical implications of metabolic phenotyping are most meaningful when the metabolic pathways of therapeutically administered drugs are known, when the functional significance of transporters involved in drug disposition is defined, and when drug concentration has been correlated to either therapeutic or

toxic effects ([Gonzalez and Idle 1994](#)). In this situation, knowledge of enzyme activity will serve as a guide to initial dosing and also allow prediction of the significance of potential drug-drug interactions.

## Drug Interactions

Drugs are frequently coadministered to achieve therapeutic effects from the combined actions at effect sites or to treat the adverse effects caused by one drug with another. Drug combinations routinely used include hypnotics with antidepressants, anticholinergic-antiparkinsonian drugs with antipsychotics, benzodiazepines with selective serotonin reuptake inhibitors (SSRIs), and mood stabilizers with antipsychotics. The use of more than one antidepressant or antipsychotic in combination for specific patients is increasingly encountered in clinical practice. When more than one drug is administered concurrently to a patient, the drugs may interact either in a positive manner or in a negative or undesired way because of either pharmacodynamic or pharmacokinetic mechanisms.

Pharmacodynamic interactions are likely to occur when an MAO inhibitor is combined with an SSRI (producing a serotonin syndrome) and when ethanol is combined with a benzodiazepine (leading to psychomotor impairment). Two drugs may have affinity for the same receptor sites in the brain and produce additive or synergistic effects, or their actions may oppose each other through antagonistic interactions at receptor sites. Most often, pharmacodynamic mechanisms are not such obvious causes of drug interactions and are less easily determined and investigated than pharmacokinetic interactions.

The kinetics of drug interactions has been extensively described and is a routine focus of clinical investigations as part of drug development ([Rowland and Matin 1973](#)). Two major mechanisms of drug interactions involve an alteration of metabolism through either induction or inhibition of hepatic CYP enzymes. Major differences exist in the pharmacokinetic consequences of these interactions. The expected changes are illustrated in [Figures 6-11](#) and [6-12](#). In [Figure 6-11](#), the steady-state plasma concentration of drug *A* following continuous intermittent dosing is altered by the addition of an enzyme inducer. After the inducer is started, the effects on the steady-state concentration of drug *A* do not occur for several days while additional enzyme that metabolizes drug *A* is synthesized. Ultimately, an increase in the metabolic clearance of drug *A* accompanied by a decrease in its steady-state plasma concentration occurs. The degree to which clearance is increased will depend on the relative importance of the particular induced enzymes in the overall elimination of drug *A* and the dose and potency of the inducer. A clinically significant example of this type of interaction is the loss of oral contraceptive effect as a consequence of carbamazepine induction of CYP3A4. The time required for a new steady state of drug *A* to occur following enzyme induction and the extent to which plasma concentrations decrease will depend on how marked a change in clearance occurs and the resulting change in drug half-life.

**FIGURE 6-11.** Predicted plasma concentration changes from the coadministration of an inducer of the metabolism of drug A.

---

**FIGURE 6-12.** Predicted plasma concentration changes from the coadministration of an inhibitor of the metabolism of drug A.

In contrast to the delayed effects of an inducer on drug A, the addition of an inhibitor causes an immediate increase in the plasma concentration of drug A (see [Figure 6-12](#)). This increase occurs as a result of a competitive inhibition of the relevant hepatic enzyme. Drug A's plasma concentration rises to a new steady state consistent with a change in its clearance. The time required to achieve the new steady state is greater than the time to achieve the initial steady state, because the half-life is now prolonged relative to its original value. The full effect of an inhibitory interaction may not be realized until the inhibitor also reaches a steady state, because the degree of inhibition will also depend on the concentration of the inhibitor ([Houston 1994](#); [von Moltke et al. 1994, 1995](#)).

Drug interactions are graded phenomena. The degree of interaction depends on the concentration of interacting drugs and, therefore, on the dose and timing of administration. Drug interactions are most likely to be detected when therapy with an interacting drug is initiated or discontinued. The clinical significance will depend on the particular drugs involved, the physiological state of the patient, the presence of concurrent illness, and other factors. Drugs with a narrow therapeutic window (concentration range) over which therapeutic effects are present without incurring toxicity are more likely to be involved in clinically significant drug interactions. Such drugs include theophylline, certain antiepileptic drugs, and antiarrhythmics. Sotalol and dofetilide are extensively used to treat atrial fibrillation, but drug interactions or dosages

that increase the drug concentration excessively can lead to a widening of the QTc interval sufficient to cause a potentially fatal *torsades de pointes* arrhythmia.

When a specific drug from a class of drugs is being selected to treat mental illness, its efficacy, safety, cost, and history of response are pertinent considerations. With the introduction of the SSRIs, the critical importance of potential drug interactions also became apparent. Some SSRIs have been shown in vitro and in vivo to be potent inhibitors of specific CYP isoenzymes ([Nemeroff et al. 1996](#); [von Moltke et al. 1994, 1995](#)). The rational selection of an antidepressant should include consideration of its potential CYP-mediated interactions with coprescribed drugs. Reviews (e.g., [Nemeroff et al. 1996](#)) have described the specific in vivo reports in more detail. Although numerous interactions are possible, their clinical significance depends on multiple factors in addition to a rise in drug concentration ([DeVane 2006](#); [Preskorn and Werder 2006](#)). Compensatory mechanisms and patterns of practice that minimize the expression of significant interactions include parallel pathways of drug elimination, dose dependence of inhibition and induction, initiation at lower starting doses, and careful attention to patient response ([DeVane 2006](#)). Although some interactions have an unequivocal high likelihood for adverse events (e.g., drug combinations that can result in a serotonin syndrome), severe adverse interactions appear to be rare events.

In vitro methods to predict in vivo interactions have appeared and are based on accepted pharmacokinetic principles ([Houston 1994](#); [von Moltke et al. 1994, 1995](#)). These screening techniques are now used extensively in the pharmaceutical industry in drug development. The expanding database on isoenzyme-specific metabolic

characteristics of new and established drugs holds promise for enabling a more informed approach to combination pharmacotherapy based on pharmacokinetic principles. The U.S. Food and Drug Administration now requires the results of testing for enzyme and transporter inhibition to be included in drug product labeling ([Lee et al. 2014](#)).

---

## Conclusion

---

The use of drugs in psychopharmacology can be problematic as a result of pharmacokinetic and pharmacodynamic variability in the dose-effect relationship. Some sources of variability can be controlled through application of pharmacokinetic principles in dosage regimen design and therapeutic drug monitoring. Improved understanding of pharmacodynamic principles permits greater individualization of dosage regimens. Knowledge regarding genetic contributions to drug response and to interactions between drugs is rapidly expanding. Future application of this knowledge will further enhance pharmacotherapy for mentally ill patients.

## CHAPTER 7

# Brain Imaging in Psychopharmacology

Ebrahim Haroon, M.D.

Helen Mayberg, M.D.

The organization and content of this chapter represent a marked change from our chapter in the previous edition of this textbook. The approach has been modified to describe how brain-imaging techniques singly or in combination are currently being used to inform contemporary research in psychopharmacology and to guide treatment selection. Although a thorough, in-depth discussion of these topics is beyond the scope of this chapter, key references will be provided to guide further reading. In addition to introducing newer research, we have retained many of the older “classic” references that continue to inform our knowledge of neuroimaging to enable readers to easily locate and access these foundational papers.

### Neuroimaging Techniques

---

*Neuroimaging* is a generic term encompassing a number of techniques and methods aimed at detecting meaningful information through the acquisition of brain images of different kinds. A first classification of these techniques may be technology based, as follows:

- *Magnetic resonance imaging (MRI)*: Based on magnetic resonance (MR) scanning equipment
- *Positron emission tomography (PET) and single photon emission computed tomography (SPECT)*: Based on tissue labeling by radioisotopes to measure brain activity

- *Electroencephalography (EEG) and magnetoencephalography (MEG)*: Enable study of brain activity and connectivity using intrinsic electrical and magnetic properties of neural circuitry

An alternative classification might be based on the types of measurement provided, as follows:

- *Vascular (hemodynamic) effects engendered by neural activity*: PET ( $\text{H}_2^{15}\text{O}$ ), functional MRI (fMRI; blood oxygenation level-dependent [BOLD] contrast, perfusion imaging), SPECT
- *Metabolic demand*: PET ( $^{18}\text{fluorodeoxyglucose}$  [ $^{18}\text{FDG}$ ])
- *Receptor density*: PET/SPECT (radioligands)
- *Neurochemistry*: magnetic resonance spectroscopy (MRS)
- *Neural connectivity*: MRI (diffusion tensor imaging), fMRI-based functional connectivity analysis
- *Surface electrical/electromagnetic effects of brain activity*: EEG/MEG
- *Structural morphometry of brain structures*: MRI

## Positron Emission Tomography and Single Photon Emission Computed Tomography

---

PET and SPECT are somewhat similar techniques in that they both use injection of radioactive tracers (radiopharmaceuticals) to assess bodily functions and to diagnose and treat disease ([National Institute of Biomedical Imaging and Bioengineering 2013](#)). The path of these radioactive tracers, which emit radioactive radiation, is picked up by specialized cameras equipped with receiving counters placed on a computed tomographic scanner. SPECT techniques rely on the emission of gamma rays, whereas PET relies on the emission of positrons. Each of these techniques has specific advantages and disadvantages that render it particularly useful for certain purposes. The unique properties of gamma ray emissions and the relative inexpensiveness of the technology have made SPECT the de facto standard for obtaining key medical imaging technology data, including myocardial perfusion imaging and scans to study bone rarefaction. Although important experiments have been conducted with SPECT, its relative lack of spatial resolution has rendered SPECT techniques less useful in studying brain functions. For this reason, most of this introduction will be devoted to PET imaging.

PET was developed from in vivo autoradiographic techniques, wherein an animal is typically injected with a biologically interesting compound synthesized with a radioisotope (e.g.,  $^3\text{H}$ ). When the animal is sacrificed, the local tissue radioactivity is easily quantified. PET requires three basic technologies: the capability to produce positron-emitting compounds, the ability to detect

simultaneously emitted gamma rays, and the computational power to reconstruct the sources of emission (Haroon et al. 2009). Positrons, or positively charged electrons (antimatter), have a particular advantage over other radioactive compounds. When a positron encounters an electron, the two annihilate each other, and their collective energy is transformed into two high-energy photons that are emitted in exactly opposite directions. Because the photons travel 180° apart, it is easy to arrange a ring of detectors to determine where the annihilation occurred. When two detectors are activated simultaneously, one knows that the emission occurred somewhere along the line connecting the two detectors. By collecting the counts over a period of time, say 60 seconds, and over a full sphere surrounding the subject's head, it becomes possible to reconstruct the geometry of the source.

Positrons are synthesized indirectly, through the radioactive decay of particular isotopes. The most commonly used isotopes (carbon-11 [ $^{11}\text{C}$ ], oxygen-15 [ $^{15}\text{O}$ ], fluorine-18 [ $^{18}\text{F}$ ], nitrogen-13 [ $^{13}\text{N}$ ]) are produced in a cyclotron by the bombardment of targets with high-energy protons. This process results in a radioactive version of a biological ion (e.g.,  $^{15}\text{O}_2$ ) that can then be used in any chemical reaction (e.g., oxidation-reduction reaction with product  $\text{H}_2^{15}\text{O}$ ). After appropriate purification procedures, these compounds can be injected intravenously into a human subject. Following injection, the isotope reaches the brain in approximately 20 seconds, where it undergoes radioactive decay due to positron emission, with decay latencies dependent on the half-life of the particular isotope (e.g., 2 minutes for  $^{15}\text{O}$ ).

Because the photons emitted during positron decay are fairly high in energy (511-keV gamma rays), they tend to pass through matter with relative ease. A specialized detector, called a scintillation detector, is required to accurately count the decays in a directional fashion. PET scanners consist of rings of scintillation detectors arranged in parallel planes. An individual detector would be constructed from a scintillating crystal, either bismuth germanate (BGO) or lutetium oxyorthosilicate (LSO), and amplification electronics. When the ionized radiation (consisting of photons or gamma rays) enters the crystal, it loses its energy (through either the photoelectric or the Compton effect), resulting in the production of electrons. These electrons further interact with the crystal, resulting in the production of visible-wavelength photons. These photons are then detected and amplified by a photomultiplier tube and converted into an electrical pulse. A "coincidence circuit" allows for identification of the detector that picks up the 180° emitted gamma ray.

Depending on the injected molecule, a particular regional distribution will occur. In the case of  $\text{H}_2^{15}\text{O}$ , it will follow the regional cerebral blood flow (rCBF). Other compounds will cross the blood-brain barrier and bind to specific receptors, in which case the distribution of radioactivity will reflect receptor concentration.  $^{18}\text{F}$ FDG, a commonly used tracer, is metabolized by hexokinase during glycolysis, like glucose. Unlike glucose-6 phosphate,  $^{18}\text{F}$ FDG is not

metabolized further but instead accumulates intracellularly, yielding a measurement of local metabolic activity ([Kennedy et al. 1976](#); [Reivich et al. 1979](#)).

## Metabolic PET Studies

Metabolic studies use  $^{18}\text{F}$ FDG to measure regional glucose metabolism.  $^{18}\text{F}$ FDG, like all  $^{18}\text{F}$  compounds, has the advantage of a relatively long half-life (110 minutes), which allows it to be synthesized in one location and administered to a subject doing a particular task in another location remote from the PET scanner while remaining trapped in brain regions according to the local metabolic rate during scanning. The main disadvantage of  $^{18}\text{F}$ FDG PET is that the compound's long half-life results in effectively no temporal resolution. Instead, it offers a snapshot of a particular brain state, time-averaged over 20–60 minutes. [Figure 7-1](#) shows functional localization of an epileptic focus in the right temporal lobe during presurgical workup.

**FIGURE 7-1.** Functional localization of an epileptic focus in the right temporal lobe during presurgical workup using magnetic resonance imaging (MRI) and fluorodeoxyglucose positron emission tomography (FDG-PET).

Most FDG uptake studies are based on the assumption that glucose uptake and neural activity at the synaptic level might be coupled. A caveat must be borne in mind when evaluating studies using FDG-PET. Glutamate, the main excitatory neurotransmitter in the brain, is removed from the synapse through a process of uptake by astroglial tissues, thereby terminating neural activation ([Magistretti and Pellerin 1999a, 1999b](#)). However, studies have shown that uptake of glutamate by astroglia can by itself stimulate glucose (and FDG) uptake ([Magistretti 2006](#); [Magistretti and Pellerin 1999a](#)). In fact, deactivation might actually be coupled with increased glucose uptake in a variety of

conditions ([Magistretti 2006](#)). Thus, the same problems that accompany studies of fMRI—i.e., whether the signal is actively excitatory versus actively inhibitory—are present in FDG-PET studies as well. Notwithstanding these limitations, PET studies have provided important information that helps to identify which patient will respond best to which treatment.

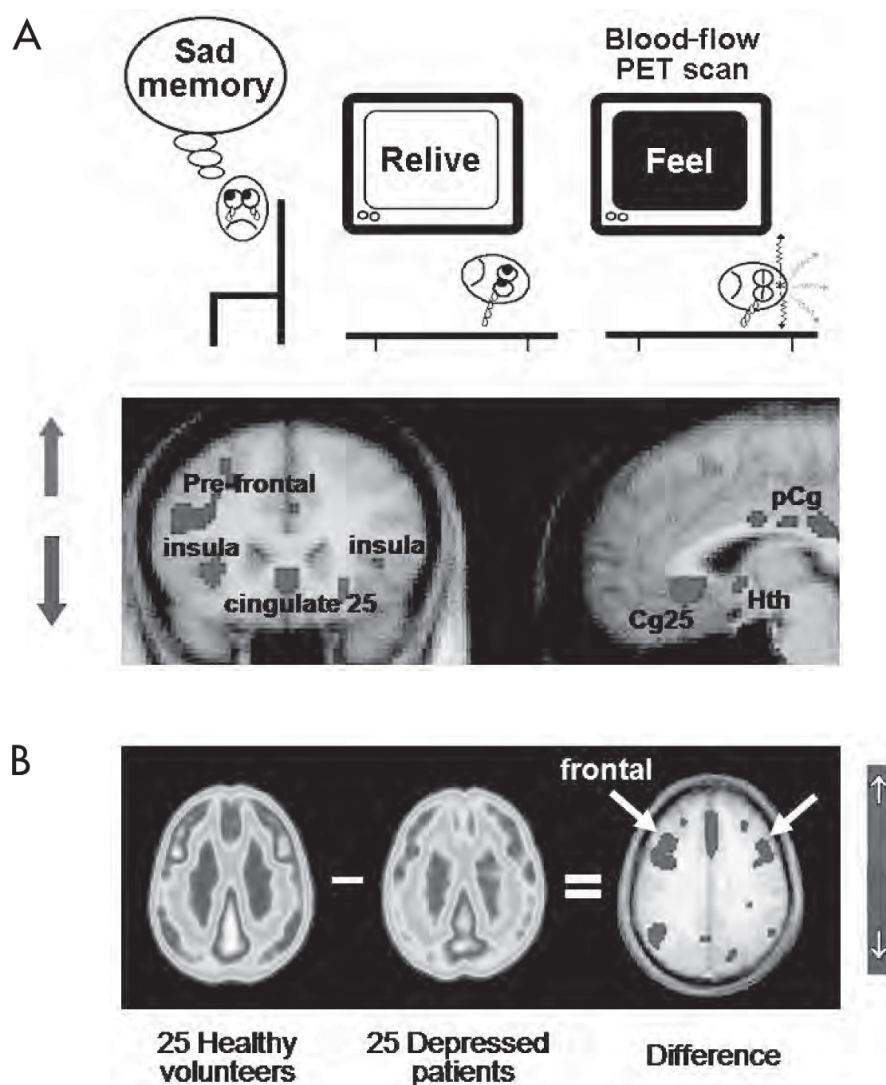

## Blood-Flow PET Studies

PET studies use  $\text{H}_2^{15}\text{O}$  to measure changes in local brain blood flow ([Herscovitch et al. 1983](#); [Mintun et al. 1984](#)). As noted earlier, blood flow is an indirect measure of local synaptic activity. Because  $^{15}\text{O}$  has a short half-life (2 minutes), several administrations can be performed during a single session. A typical  $\text{H}_2^{15}\text{O}$  study would have 8–16 injections and scans for each subject. The experimental design would manipulate the task that the subject performs during each scan. Each scan lasts about 1 minute, with 8–10 minutes between scans (5 half-lives).  $\text{H}_2^{15}\text{O}$  studies not only allow for multiple conditions to be studied but also allow for repetition of conditions, increasing the statistical power of the studies. The main disadvantage is that because of the short half-life, the  $\text{H}_2^{15}\text{O}$  must be produced reliably and in close proximity to the scanner. PET  $\text{H}_2^{15}\text{O}$  studies are increasingly being replaced by perfusion MRI studies—mostly because of the latter’s greater ease of use, decreased radiation safety concerns, and better spatial resolution.

## Metabolic and Blood-Flow PET Studies in Neuropsychiatry

PET has been used to assess functional activity of brain regions, both in the resting state and in response to various stimuli. [Figure 7-2A](#) shows a picture of increased cerebral blood flow (CBF) to paralimbic regions during a sad-mood induction task (to be described later) using  $\text{H}_2\text{O}$ -PET. In contrast, [Figure 7-2B](#) shows metabolic activity differences among depressed versus healthy patients using FDG-PET. These modalities have been effectively used to study a variety of mental phenomena and have been of considerable benefit in enhancing our understanding of psychiatric disorders. Of particular interest have been studies using PET to investigate the biological basis of schizophrenia ([Fujimoto et al. 2007](#); [Lange et al. 2005](#)), bipolar disorder ([Post et al. 2003](#)), depression ([Mayberg 2003b](#); [Neumeister et al. 2004](#)), substance abuse and craving ([Kilts et al. 2004](#)), posttraumatic stress disorder (PTSD) ([Bremner 2007](#)), attention-deficit/hyperactivity disorder (ADHD) ([Schweitzer et al. 2004](#)), and Alzheimer’s disease ([Small 1996](#)). Most PET studies of psychiatric disorders have shown generally similar patterns of resting blood flow and metabolic abnormalities.

That said, such identified patterns have not yet proved adequately consistent to warrant use of PET as a diagnostic procedure in individual patients. Notably, only resting-state FDG-PET scanning has undergone sufficient repeated sensitivity and specificity testing to be considered useful and reliable for the diagnosis of Alzheimer's disease in patients with progressive neurocognitive disturbance and presumed dementia (Silverman et al. 2002). Nonetheless, research studies using these methods have provided many new insights into the pathophysiology of the disease and the mechanisms mediating treatment response (Erritzoe et al. 2003; Evans et al. 2006; Mayberg 2003a; Roffman et al. 2005). In a similar manner, functional imaging techniques have been combined with neurosurgical treatments such as deep brain stimulation (DBS) to study brain-imaging biomarkers of treatment response (Carbon and Eidelberg 2002).

## Receptor-Labeling PET Studies

PET-based receptor imaging has provided a window for viewing the complex functioning of brain systems that mediate treatment response to psychopharmacological agents (Gunn et al. 2015). A snapshot of available radionuclide-binding modalities is provided in Table 7-1. With use of PET-based radioligands, it has been possible to visualize density, distribution, and occupancy of neural receptors and transporters before, during, and after drug therapy (Gunn et al. 2015; Talbot and Laruelle 2002). Receptor studies use radioligands—chemicals incorporating a positron-emitting isotope into a molecule whose pharmacokinetics are already known (Gunn et al. 2015). Ideally, these ligands bind specifically to one receptor type. Most of these studies are of the mapping type, which shows the distribution of a particular receptor in the brain (e.g., dopamine type 2 [D<sub>2</sub>] receptor). Here, the measured radioactivity reflects both the local concentration of receptors ( $B_{\max}$ ) and the affinity of the ligand for the receptor (measured by  $K_D$ , the equilibrium dissociation constant). If the ligand acts as a competitive antagonist, then the *apparent* affinity is also affected by the concentration of the endogenous neurotransmitter. The analysis can be simplified by considering the ratio of  $B_{\max}$  to  $K_D$ , termed the *binding potential*. Ligands undergo both specific and nonspecific binding. Typically, one is interested only in the specific binding (i.e., to the receptor of interest). Use of a reference tissue that is known to have a low receptor concentration allows one to subtract out the nonspecific binding (e.g., the cerebellum has a low concentration of D<sub>2</sub> receptors). In this case, the difference in distribution for the two tissues is directly proportional to the binding potential. Ligands require a more involved synthesis than either water or <sup>18</sup>F-DG, and their use is a race against the clock as the isotope decays. The end product must meet several requirements: high specific activity (amount of radioactivity per mole), high radiochemical purity, and sterility. <sup>18</sup>F ligands are easier to synthesize because of their long half-life, but <sup>11</sup>C ligands (20-minute half-life) have a higher potential for biological relevance. Appropriate availability of neurotransmitters and neuromodulators is essential to normal neurological and psychological function. Dysfunction or degeneration of neurons that synthesize these substances can lead to various disorders. In the following sections, specific examples will be

provided to illustrate the use of imaging methods to answer pertinent questions of relevance to psychopharmacology.

### **Dopamine PET Imaging**

Parkinson's disease is caused by selective degeneration of the dopamine-synthesizing neurons of the nigrostriatal system. Uptake of 3,4-dihydroxy-6-18F-fluoro-L-phenylalanine ([<sup>18</sup>F] DOPA), which selectively labels aromatic L-amino acid decarboxylase (AADC), a critical enzyme in the synthesis of dopamine, has been used to estimate both the number of surviving cells and AADC activity among nigral neurons, thus providing a tool to understand the connection between dopamine dysfunction and clinical symptom evolution ([Cropley et al. 2006](#); [Ravina et al. 2005](#)). PET imaging has been used to identify binding sites of neurotransmitters of relevance to psychiatric disorders, in order to characterize patients and inform treatment decisions based on mechanisms of drug action. For instance, studies with ligands that bind to D<sub>2</sub> receptors have informed us that lower binding affinity, faster dissociation, and optimal occupancy at usually prescribed doses of D<sub>2</sub> receptor antagonists might form the basis of atypical antipsychotic drug action ([Kapur and Remington 2001](#)). Dopamine transporter (DAT)-labeling PET ligands have also been used to study cognitive and motor dysfunction in Parkinson's disease ([Cropley et al. 2006](#); [Ravina et al. 2005](#)) and are currently being used to investigate psychiatric disorders such as ADHD.

### **Serotonin PET Imaging**

PET scanning with [ $^{11}\text{C}$ ] methyl-L-tryptophan, which is a marker of serotonin (5-hydroxytryptamine [5-HT]) synthesis, is being used to identify overactive serotonin-synthesizing systems to differentiate epileptogenic from nonepileptogenic lesions in tuberous sclerosis prior to neurosurgery (Luat et al. 2007). Synaptic turnover of serotonin secretion is regulated by two processes—reuptake mediated through SERT and negative feedback mediated through serotonin type 1A (5-HT<sub>1A</sub>) autoreceptors. PET tracers can be used to study both of these processes. Antidepressant drugs that bind to and inhibit the serotonin transporter (SERT) have been shown to be associated with symptomatic recovery from depression (Nemeroff and Owens 2009). Radioligands that specifically bind to SERT, such as [ $^{11}\text{C}$ ] 3-amino-4-(2-dimethylaminomethyl-phenylsulfanyl)-benzonitrile ( $^{11}\text{C}$ -DASB), have been used to estimate and associate SERT-occupancy rates of selective serotonin reuptake inhibitors (SSRIs) with clinical efficacy (Meyer 2007). Along similar lines, the role of SERT in suicidal behavior has been investigated in studies using SERT-binding PET ligands (Purselle and Nemeroff 2003). Downregulation of 5-HT<sub>1A</sub> receptors has been putatively linked to antidepressant efficacy and to the delay in onset of symptom response after initiation of SSRI treatment (Blier and Ward 2003). Radioligands such as [ $^{11}\text{C}$ ] WAY-100865 have been used to profile changes occurring in 5-HT<sub>1</sub> receptors before, during, and after antidepressant treatment (Fisher et al. 2006). Finally, studies using agents such as  $^{18}\text{F}$ -altanserin have demonstrated that increased binding of downstream postsynaptic serotonin type 2A (5-HT<sub>2A</sub>) receptors in frontal cortex (Brodmann area [BA] 9) was associated with increases in pessimism and self-injurious and suicidal behavior, thereby adding to our understanding of suicidal behavior and depression (Kumar and Mann 2014; Meyer et al. 2008). These methods are likely to lead to reformulation of treatment practices used in the management of depressive disorders and at the same time explain how imbalances in the serotonergic system might disrupt mood-regulating neural circuitry, resulting in depressive disorders (Fisher et al. 2006).

### **Gamma-Aminobutyric Acid SPECT Imaging**

Alterations in the function of  $\gamma$ -aminobutyric acid (GABA) systems in PTSD (Bremner 2007) and panic disorder (Bremner et al. 2000) have been reported on the basis of decreased binding of ( $^{123}\text{I}$ )-iomazenil to benzodiazepine receptors in the BA9 region of patients with these disorders.

### **Amyloid PET Imaging**

Neurodegenerative disorders such as Alzheimer's disease have acquired critical relevance, given the larger proportion of aging population in modern society. Because the pathological changes associated with neurodegeneration (e.g., beta-amyloid deposits, neurofibrillary tangles, decreased metabolic activity) often precede clinical disease by several decades, early identification of these

changes is of paramount importance. PET tracers for amyloid imaging can be roughly classified into  $^{18}\text{F}$ - and  $^{11}\text{C}$ -based tracers.  $^{18}\text{F}$ -based ligands include [ $^{18}\text{F}$ ] FDDNP ([Small et al. 2006](#)), and at least three commercially developed, U.S. Food and Drug Administration-approved amyloid-labeling PET tracers are available for clinical use: florbetapir ([ $^{18}\text{F}$ ] AV-45 [Amyvid], Eli Lilly), flutemetamol (Vizamyl, GE Healthcare), and florbetaben ([ $^{18}\text{F}$ ] BAY94-9172 [Neuraceq], Piramal Imaging).  $^{11}\text{C}$ -based tracers include [ $^{11}\text{C}$ ] PIB (Pittsburgh Compound-B) ([Klunk et al. 2004](#)) and [ $^{11}\text{C}$ ] SB (stilbene) derivatives ([Ono et al. 2003](#)). [ $^{11}\text{C}$ ] PIB in particular has garnered the lion's share of research studies and continues to inform the development of other amyloid-labeling agents. For further information on this rapidly evolving field, readers are referred to the authoritative review of [Vlassenko et al. \(2012\)](#). More recent data pointing to tau accumulation as an earlier marker of neurodegeneration have led to increased interest in the development of new tracers to map tau rather than amyloid deposition ([Dani et al. 2016](#)). PET-based amyloid and tau-imaging tracers have the potential to help identify patients with mild cognitive impairment (MCI) who are at increased risk of converting to dementia ([Mathis et al. 2005](#)). However, it needs to be mentioned in passing that therapies based on combating amyloid deposition have not yielded much success in reversing the course of Alzheimer's disease.

## Microglial PET Imaging

Neuroinflammatory activation has been implicated as a pathogenic factor in patients with a wide range of psychiatric disorders ([Haroon et al. 2012](#)). The precise nature and meaning of these neuroinflammatory changes across various disorders have not yet been clearly delineated. At least some of these neuroinflammatory changes might be mediated through the activation of resident immune cells—namely, the microglial cells, which when activated express a characteristic 18-kDA translocator protein (TSPO). Several PET ligands that label the TSPO binding site have been synthesized and made available for research. The first TSPO ligand to become available was [ $^{11}\text{C}$ ] PK11195 ([Myers et al. 1991](#)), which showed increased microglial activation in several neurological and psychiatric disorders. Initial enthusiasm for this ligand was tempered by the discovery of its high level of nonspecific binding to nonmicroglial tissue (including platelets, plasma proteins, and monocytes) and of the high quantities of TSPO in healthy blood-brain barrier regions, thus reducing the specificity of the signals. Two other compounds reported to have greater specificity in microglial TSPO labeling—including one  $^{11}\text{C}$ -based compound ([ $^{11}\text{C}$ ] PBR28 [[Brown et al. 2007](#)]) and one  $^{18}\text{F}$ -based compound ([ $^{18}\text{F}$ ] FEPPA [[Rusjan et al. 2011](#)])—have been proposed.

The field continues to struggle with many methodological issues. A recent study showed that [ $^{18}\text{F}$ ] FEPPA binding was significantly elevated in prefrontal cortex, insula, and anterior cingulate cortex (ACC) brain regions in depressed

subjects compared with healthy controls ([Setiawan et al. 2015](#)). This finding is important for improving treatment because it implies that therapeutics that reduce microglial activation should be promising for major depressive disorder. On the other hand, two studies of schizophrenic patients have been reported, with the first, using [ $^{18}\text{F}$ ]-FEPPA, reporting negative findings ([Kenk et al. 2015](#)) and the second (not yet published), using [ $^{11}\text{C}$ ]-PBR28, reporting positive findings clouded by the confounding effects of disease pathology and age ([Turkheimer et al. 2015](#)). A recent review ([Turkheimer et al. 2015](#)) summarized three main problems affecting quantification of PET TSPO ligands in the brain—namely, 1) genomic variation (a nucleotide polymorphism in the TSPO gene (rs6971) leads to population-level variation in binding affinity for TSPO tracers); 2) the very high affinity of some of the novel ligands disproportionately increases the TSPO signal at blood-brain barrier regions compared with the signal at the tissue; and 3) the difficulties in obtaining accurate estimates of plasma concentrations of the tracer to be used as a reference value. For a more detailed explanation of the challenges involved in obtaining meaningful data, readers are referred to the excellent review by [Turkheimer et al. \(2015\)](#).

## Magnetic Resonance Imaging

---

The basis of MRI technology rests on the magnetic properties of the ions that constitute the underlying tissues. In most biological tissues, these magnetic properties are based on the hydrogen atom, which, as a component of water, is found ubiquitously in organic tissues (water constitutes roughly 80% of brain weight). The nucleus of a hydrogen atom, a single proton, has an intrinsic magnetic property known as moment, or spin, along its axis. The protons in tissue are normally oriented in random directions, but if a powerful external magnetic field is applied, the protons will tend to align in the north/south direction, the more powerful field. Spins can orient either in the direction of the applied field (*parallel*) or in the direction opposite to it (*anti-parallel*), but on average the parallel orientation tends to dominate. This situation results in a net magnetic moment induced by the external field in the tissue; in other words, the tissue becomes slightly magnetized. The intensity of the induced magnetization depends on the proton distribution (i.e., on the local molecular characteristics of the tissue). The strength of the magnetic field used in MR scanners is quantified in terms of *tesla*; currently available clinical scanners range in strength from 1.5 tesla to 3.0 tesla, and the range is even higher for research scanners (up to 7.0 tesla). The magnetic fields generated by these scanners are very strong, consequently leading to intense magnetization and heat generation in any metallic objects placed in or near the scanners. This often leads to safety procedures involving screening for any metallic objects such as metallic clips or implants.

MRI technique primarily involves perturbing the molecular protons aligned parallel to the magnetic field generated by the scanner magnet. This instrumental perturbation (stimulation) is performed by applying short radiofrequency (RF) pulses that, when appropriately tuned to a precise frequency, are able to transiently tip the orientation of the spins away from the applied magnetic field. However, the tendency of the spins is to return to their original orientation coherent with the applied magnetic field, given that the latter state is characterized by a lower energy (in a baseline resting state) known as “relaxation” state. Given that the relaxation of the protons results in a change from a high-energy to a low-energy state, the extra energy is generated as an RF wave, which can be detected by the same RF hardware device that emits the excitation pulses. In MR terminology, this device, referred to as the “transmit-receive” RF coil, has the form of a small cylindrical cage that surrounds the subject’s head in the scanner. The emitted RF wave—or, more precisely, the temporal signature of its decay as the excited spins relax—constitutes the actual MR signal and depends on the molecular characteristics of the local tissue, as well on the particular sequence of excitation pulses employed. The details of the physics that specify how the RF pulse sequences can be engineered to acquire images of the brain with different physiological meanings are beyond the scope of this discussion, and the interested reader is directed elsewhere ([Buxton 2002](#)).

The spin relaxation measured with MRI can be decomposed into longitudinal and transverse components, which are only partially related. Measurement of the relaxation time of the longitudinal component, called *T1*, provides images in which the contrast between different types of tissue (notably, gray matter, white matter, and cerebrospinal fluid) is maximized. Such *T1-weighted images* are capable of defining the anatomy of the living brain with great precision and are therefore used as an anatomical reference for most of the neuroimaging studies. An image of the entire brain with a resolution, or voxel size, of  $1\text{ mm}^3$  (*voxel* stands for “volume pixel,” the unitary element used in MR imaging of the three-dimensional space into which the cortex is divided) can be acquired on a 1.5-tesla clinical scanner in less than 6 minutes.

Measurement of the relaxation time of the transverse component (*T2*), which can be divided into the *T2* and the *T2\** characteristic times, provides images that are influenced by the local inhomogeneity of the magnetic field, which is induced by blood-perfusion patterns or lesions including infarcts or tumors. Hence, *T2-weighted* imaging is also used to identify lesions in the brain not picked up by the *T1* scans. In particular, *T2\*-weighted* images are characterized by a contrast that highlights changes in vascular dynamics that accompany neural activity and are thus employed in functional mapping studies. The advent of a very fast technique for the acquisition of *T2\*-weighted* images, called *echoplanar imaging* (EPI), allows collection of an entire brain volume in 3–4 seconds and has been instrumental in the rapid development of fMRI. The ultrarapid acquisition of MR signals during EPI tends to diminish the *T2\** signal, which becomes negligible

when averaged over several smaller voxels. This diminished signal limits the resolution of standard EPI images, which typically expand to a voxel size of 3–4 cu mm (which is larger than the 1 cu mm voxel size of conventional MRI images), thereby constraining the use of EPI in advanced MR imaging. Thus, EPI images will not be able to provide the submillimetric precision required to visualize columnar organization of the visual cortex (Menon and Goodyear 1999). Table 7-2 lists common applications of MR-based technologies in psychopharmacology research. These techniques will be described in greater detail in the following section.

## Functional Magnetic Resonance Imaging

*fMRI* refers to a variant of MRI that sensitively records local changes in regional blood flow resulting from neural activity. The increase in regional blood flow, as engendered by neural activation, results in oxygen consumption that exceeds the oxygen available in the tissues. The higher oxygen consumption causes an apparent *decrease* in deoxyhemoglobin in the activated brain region, leading to a change in the RF perturbation qualities of the local tissue. In the 1930s, Linus Pauling observed that the amount of oxygen carried by hemoglobin is inversely proportional to the degree to which it perturbs a magnetic field. This property of differential magnetization was finally demonstrated in vivo in the late 1980s, and fMRI was born (Ogawa et al. 1992; Thulborn et al. 1982). Many reviewers have considered the relative merits and demerits of fMRI versus PET imaging techniques. A brief summary of the various MR imaging techniques in current research on neuropsychiatric disorders is provided in Table 7-2.

### The BOLD Signal in fMRI

Functional MRI exploits the fact that deoxyhemoglobin has paramagnetic properties and oxyhemoglobin does not. Deoxyhemoglobin disturbs the local

magnetic environment, causing the surrounding protons to dephase even faster than they would otherwise ([Figure 7-3](#)).

**FIGURE 7-3.** Schematic diagram of the effect of hemoglobin (Hb) on the local magnetic field of brain tissue.

Only deoxyhemoglobin (deoxyHb) has paramagnetic properties and locally distorts the field, leading to faster spin dephasing.

Heightened neuronal activity leads to an increase in blood flow, accompanied by a decrease in the amount of deoxyhemoglobin relative to oxyhemoglobin. Because lower deoxyhemoglobin means reduced rapid-spin dephasing, this

increase in blood flow appears as an increase in the MR signal—a phenomenon called the BOLD signal. In response to a regionally specific neuronal activation, the BOLD signal usually increases by about 1% on a standard 1.5-tesla clinical scanner. The intensity of the signal is proportional to the strength of the main magnetic field—for example, the intensity will double in the case of a 3-tesla scanner. The temporal resolution of fMRI is determined both by the hemodynamic response and by the physical constraints of the scanner magnetic fields. The hemodynamic response generally lags behind the neural activity by 3–5 seconds and may last for up to 10–15 seconds (Figure 7-4).

**FIGURE 7-4.** Relative blood oxygenation level-dependent (BOLD) response to 1-second visual stimulation.

These functional magnetic resonance imaging (fMRI) data are from the occipital cortex and were obtained in a healthy volunteer in a 3-tesla scanner. The amplitude of the signal is about 2%, with the peak 5–8 seconds after the stimulus.

The rate at which the scanner can acquire images is influenced by the desired resolution. Generally, the more slices and the finer the resolution within each slice, the longer a whole-brain acquisition takes. Whereas an individual slice can be acquired in as little as 60 milliseconds, whole-brain imaging usually requires about 2–3 seconds. In contrast to the ease with which fMRI measurements can be performed, there are specific limitations with BOLD imaging:

- **Spatial errors.** The BOLD effect originates from venous vessels (capillaries, venules, and veins), so the signal is not exactly collocated either with the locus of neural activity or with the arterial supply. This spatial error may, however, be negligible for brain-mapping studies employing a standard spatial resolution (voxel size  $\sim 50\text{ mm}^3$ ).
- **Bulk head motion and physiological pulsation (heart pulse, respiration) artifacts.** To reduce motion, head movement should be restrained while maintaining a comfortable situation for the subject.
- **Susceptibility artifacts.** The fact that BOLD detects local changes in magnetic susceptibility (due to the variation in deoxyhemoglobin concentration) renders it vulnerable to the large discontinuity that exists at the interfaces between bone/air and bone/liquid. In these regions, the steep variations in tissue density cause a distortion of the local magnetic field, resulting in both a spatial distortion of the image and a drop in the BOLD signal. These spatial distortions make it difficult to detect the small changes associated with deoxyhemoglobin variations. The problematic regions are notably the orbitofrontal cortex and the inferior part of the temporal lobes, which unfortunately are the loci of many interesting neuropsychological processes.

**Functional Imaging: PET-Based Versus fMRI-Based Methods**

At this juncture, it might be helpful to draw a distinction between functional imaging paradigms using PET-based methods and those using fMRI-based methods. Table 7-3 provides a comparison of the advantages and disadvantages of the two imaging techniques.

---

**TABLE 7-3. Advantages and disadvantages of positron emission tomography (PET) versus functional magnetic resonance imaging (fMRI)**

---

**Advantages of PET versus fMRI**

- Quiet (good for acoustic stimulation); fMRI may have noise >90 dB
- Less sensitive to movement artifact
- Allows metabolic and receptor mapping
- Allows imaging of brain regions that are typically difficult to image with fMRI because of the presence of a susceptibility artifact (orbitofrontal cortex,

inferior temporal lobe) that causes both distortion and loss of signal  
Allows the use of standard measurement devices (physiological, behavioral) inside the scanner (i.e., avoids the complication of the need for specially designed MRI-compatible hardware) (In the MRI environment, the presence of a very strong static magnetic field commands the use of diamagnetic components; moreover, every electric device in the scanner room needs to be carefully shielded to prevent interference problems to and from the scanner. Scanning is not used in patients who have pacemakers or ferromagnetic metal parts in their bodies.)

### **Disadvantages of PET versus fMRI**

Injection of a radioactive isotope precludes the use of PET for longitudinal studies in which the same subjects are scanned repeatedly over an extended period of time.

PET provides an integral measure (over time) of brain activity (for activation techniques), with a temporal resolution on the order of minutes because of the lifetime of the isotope. By comparison, fMRI has a temporal resolution on the order of seconds. This prevents the use of sophisticated, event-related designs with PET. Also, the number of images typically collected with PET on a single subject rarely exceeds a dozen, thereby limiting the statistical treatment in the analysis of the data.

Spatial resolution is more limited with PET than with fMRI.

Cyclotron must be located nearby.

PET is more expensive than fMRI (utilization costs per hour: fMRI, ~ \$500; PET, ~ \$2,000).

The acquisition procedure is time-consuming and requires more resources. (One scan typically lasts ~ 3 hours [fMRI typically lasts <1 hour]. In comparison, the MRI experimental setup is easier to perform and can be operated by just one person.)

### **Functional Imaging: Neural Activation Studies Versus Resting-State fMRI Studies**

In the decade since publication of the previous edition of this textbook, the technique of functional imaging (PET or BOLD-MRI based) has undergone considerable evolution. Functional MRI studies may be divided into two key types: 1) neural activation studies, which profile increases and/or decreases in regional BOLD response to a specific stimulus, and in which activity changes that deviate from the norm can be assumed to reflect altered tissue functioning due to pathology); and 2) studies that examine interregional connectivity between brain regions during a nonactivated or “resting” state. These two approaches will be described in further detail in the following sections.

## **Neural activation paradigms in psychopharmacological research.**

At the time of writing this chapter, most of the applications of fMRI techniques are still experimental—for example, helping investigators to map areas of functional activation in response to cognitive and affective tasks. However, several of these techniques have begun to provide key clinical information about mechanisms of new treatments and to shed more light on the action of older treatments. Similarly, several novel and innovative uses of imaging methods have been described in the literature.

*Mood and self-referential paradigms.* A core feature of depression involves negative bias and anhedonia, suggesting specific alterations in neural pathways mediating salience, self-reference, and reward. Accordingly, several fMRI studies have reported failed activation of dorsomedial prefrontal cortex (BA10) in depressed patients in response to positive words or pictures ([Lemogne et al. 2009](#); [Mitterschiffthaler et al. 2003](#)). Interestingly, activation of the dorsomedial prefrontal cortex is also seen in tasks requiring self-referential processing in healthy subjects ([Craig et al. 1999](#); [Fossati et al. 2003](#)). A study using an emotional “Go/No-Go” task identified a depression-specific pattern consisting of blunted responses in reward circuits in response to neutral words but exaggerated responses in self-referential areas of the rostral cingulate and medial frontal cortex in response to sad words ([Elliott et al. 2002](#)). Such sensitive tasks can plausibly be used as outcome measures in the evaluation of the efficacy of antidepressant treatments.

*Facial-expression-processing paradigms.* Another task frequently used in neural activation studies across a range of disorders involves presentation of faces with different emotional expressions, such as angry, sad, fearful, happy, and neutral. Such faces are either overtly presented or hidden behind a mask, depending on the study hypothesis. With overt presentation, subjects typically perform a behavioral task related to classifying some aspect of the faces. Application of such tasks in fMRI studies has produced a large amount of data regarding the neural basis of emotional processing in healthy subjects, demonstrating robust activation of the amygdala in response to emotional faces ([Whalen et al. 1998](#)). Of note, patients with depression, anxiety disorders, or PTSD exhibit increased amygdala responses to the presentation of fearful or angry faces ([Rauch et al. 2000](#); [Shin et al. 2004](#); [Whalen et al. 2002](#)). Facial-expression-processing paradigms have also proved useful in evaluating treatment effects in response to antidepressant drugs ([Sheline et al. 2001](#)), as well as in studying temperamental or genetic contributions to emotional processing ([Hariri et al. 2002](#); [Stein et al. 2007](#)). Similar strategies have identified antidepressant-induced changes with other tasks ([Fu et al. 2007](#)).

*Cognitive “working memory” paradigms.* The “*n*-back” task is a working memory task that captures prefrontal cortical function; it has been used in fMRI

studies to identify altered neural functioning in a variety of disorders, including schizophrenia and depression ([Abdallah et al. 2014](#); [Meyer-Lindenberg and Weinberger 2006](#)). The *n*-back test involves visual presentation of letter stimuli at previously chosen intervals and epochs (e.g., 2-second interval for 30-second epochs) ([Owen et al. 2005](#)). The baseline (control) condition is usually a 0-back condition in which subjects are required to press a button with the right index finger when the stimulus (e.g., the letter “x”) appears. In the experimental condition (1-, 2-, or 3-back), subjects are required to press a button if the presented stimulus is the same as a stimulus presented *n* trials previously (*n*=1, *n*=2, or *n*=3). The task difficulty and the condition are varied in a previously specified order throughout the scan time. Subject performance during scanning in regard to accuracy (number of target stimuli correctly identified) and response time is usually recorded. Increased prefrontal activity is seen in depressed patients relative to control subjects performing this task, an effect amplified by task difficulty ([Harvey et al. 2005](#)). On the other hand, several studies have reported that schizophrenic patients demonstrate deficits in activation of the prefrontal cortex during this task, thought to reflect alterations in dopamine functioning. Normalization of neural activation patterns by antipsychotic drugs is associated with response to treatment. The *n*-back task has also been useful in identifying genetic contributions to schizophrenia risk ([Meyer-Lindenberg and Weinberger 2006](#)). [Bookheimer et al. \(2000\)](#) used a verbal memory paradigm—in which patients memorized unrelated pairs of words during scanning—to study hippocampal activation in patients at risk of developing Alzheimer’s disease. Not only did the carriers of the apolipoprotein E epsilon 4 (*ApoE-ε4*)+ + allele (associated with a higher risk of dementia) show greater hippocampal activation, but this baseline activation pattern predicted longitudinal cognitive decline.

*Reward-processing paradigms.* Reward processing is believed to represent a complex psychological function incorporating a wide range of goal-directed, hedonic behaviors, including motivation, salience, anticipation, experiencing pleasure, and satiety ([Whitton et al. 2015](#)). Most recent data appear to strongly support the presence of aberrant reward-processing activity across multiple psychiatric disorders (transdiagnostic and transnosological biomarker) ranging from major depressive disorder and substance use disorders to bipolar hypomanic episodes and schizophrenia ([Whitton et al. 2015](#)). Reward-processing paradigms are commonly used in studying substance use and craving, and also in studying anhedonia in both depression and schizophrenia ([Whitton et al. 2015](#)). In addiction studies, typically the patient, while lying in a scanner, is presented with multiple contexts associated with drug abuse, and activation of reward-processing circuitry is studied. [Zink et al. \(2006\)](#) used fMRI to study activation of the basal ganglia (a key component of reward circuitry) in healthy volunteers in response to salient stimuli with high motivational relevance. [Figure 7-5](#) illustrates activation of salience and reward-processing

brain regions during a monetary reward task, as visualized with fMRI. The concept of “temporal (or delay) discounting” refers to the extent to which an individual will choose a discounted immediate reward over a delayed reward that is much higher in value. Patients with DSM-IV ([American Psychiatric Association 1994](#)) impulse-control disorders, such as pathological gambling, have been found to show considerable variation in their tendency to use temporal discounting. Studies using fMRI reported that increased activation of paralimbic cortex was observed when subjects chose smaller/earlier rewards, whereas frontoparietal activation was seen when subjects chose larger/later rewards ([Dixon et al. 2006](#); [McClure et al. 2004](#)). Studies of delay discounting might help us develop brain activation-based biomarkers of complex disorders such as DSM-5 ([American Psychiatric Association 2013](#)) substance-related and addictive disorders (including gambling disorder). In a recent study, a combination of [ $^{18}\text{F}$ ] DOPA PET and fMRI was used to demonstrate that decreases in dopamine synthesis resulting from inflammatory activation could lead to decreased activation of the ventral striatal regions in response to potentially rewarding stimuli, which in turn could be correlated with anhedonia ([Capuron et al. 2012](#)).

In conclusion, these examples illustrate the potential of fMRI activation studies in probing brain-behavior relationships in psychiatric disorders, owing to the flexibility of fMRI paradigm design as well as the large variety of standardized tasks and possibility of developing novel tasks.

**Resting-state fMRI studies: neural networks and functional connectivity analysis.** Resting-state neural cells manifest spontaneous activity that triggers a tiny but demonstrable BOLD effect, which (in contrast to other BOLD activations) shows pulsation at much lower frequencies (0.01–0.03 Hz). These low-frequency pulsatile BOLD fluctuations have been shown to be remarkably synchronous among connected structures operating within a neural network designed to execute a specific function ([Biswal et al. 1997](#); [Lowe et al. 2002](#)).

Study of large-scale brain networks that mediate cognitive and affective functions might provide key insights into dysfunctional brain architecture ([Menon 2011](#)). Graph-theory approaches have been used to further refine data obtained using resting-state BOLD MRI data. Brain networks involve collections of brain regions (nodes) and connections (edges), both of which are defined using structural diffusion tensor imaging or resting functional connectivity analysis measured using BOLD fMRI ([Bullmore and Sporns 2009](#)). Damage to nodes or edges from disease processes can lead to aberrant signaling affecting whole networks or subnetworks, often leading to psychiatric syndromes and symptoms. Organizationally, the neural systems involved in regulation of affect and behavior are believed to involve three core intrinsically connected networks:

1. **Central Executive Network (CEN):** A frontoparietal network anchored in primary nodal regions involving dorsolateral prefrontal cortex (DLPFC) and posterior parietal regions responsible for actively maintaining and manipulating information in the working memory and making decisions in the context of goal-directed behavior ([Seeley et al. 2007](#)). A large number of studies have documented abnormalities of the CEN in most psychiatric disorders, but most importantly in schizophrenia ([Forbes et al. 2009](#); [Woodward et al. 2011](#)) and depression ([Miller et al. 2015](#)).
2. **Default Mode Network (DMN):** In contrast to the CEN, the DMN preferentially shows greater activity during restful or passive cognitive states ([Buckner and Vincent 2007](#); [Gusnard et al. 2001](#)) and is primarily anchored in the posterior cingulate and the inferior parietal and medial frontal cortices. High activity in these regions during periods of wakeful rest and passive self-reflection have led some to hypothesize that such activity may serve to “consolidate the past, stabilize brain ensembles, and prepare us for the future” ([Buckner and Vincent 2007](#), p. 1066). Abnormalities in the functional connectivity of this network in psychiatric disorders such as schizophrenia ([Bluhm et al. 2007](#)), depression ([Greicius et al. 2007](#)), dementia ([Rombouts et al. 2005](#)), autism ([Cherkassky et al. 2006](#)), and multiple sclerosis ([Lowe et al. 2002](#)) have been reported.
3. **Salience Network (SN):** The SN is anchored primarily in the dorsal ACC and fronto-insular cortex and is believed to be involved in detecting and integrating relevant interoceptive, autonomic, and emotional information

([Seeley et al. 2007](#)). Dysfunction of this network has been consistently associated with anxiety, pain syndromes, and addiction ([Klumpp et al. 2013](#); [Menon 2011](#); [Paulus and Stein 2006](#)).

## Magnetic Resonance Spectroscopy

MRS technology is based on the fact that MR acquisition involves receiving echoed RF waves of multiple cellular chemical constituents. The individual chemical and metabolite constituents could be measured by suppressing the resonance frequency of water molecules. A detailed exposition of the various types of MRS techniques is beyond the scope of this chapter, and the reader is referred to excellent reviews on the topic ([Mason and Krystal 2006](#); C.M. [Moore et al. 1999](#)). Among the markers currently being researched are *N*-acetylaspartate (NAA), glutamate/glutamine, myo-inositol, choline, glutathione, creatine, GABA, phosphomonoester, and phosphodiester ([Lyoo and Renshaw 2002](#)). An example of an MRS spectrum from a healthy control subject is provided in [Figure 7-6](#). Using proton MRS ( $[^1\text{H}]$ -MRS), [Frye et al. \(2007\)](#) were able not only to demonstrate elevated glutamate/glutamine in anterior cingulate/medial prefrontal areas of patients with bipolar depression but also to document reduction of glutamine among patients who showed clinical response to treatment with lamotrigine. Glutamate elevation during MRS is believed to be one of the most consistent findings in bipolar disorder among children and adults ([Gigante et al. 2012](#); [Yüksel and Öngür 2010](#)). Using another sample of adult patients, these same authors reported that ACC glutamine levels were elevated rapidly following administration of the anticonvulsant topiramate (C.M. [Moore et al. 2006](#)). A study using MRS technology reported that cortical GABA concentrations increased following a course of electroconvulsive therapy (ECT) and used this information to hypothesize that this increase in GABA might be associated with clinical recovery ([Sanacora et al. 2003](#)).

At present, MRS remains the only in vivo method of measuring glutamate among humans, albeit not without problems. Profiling brain response to inflammation is of great importance to better understand the biological basis of mental disorders. Brain and behavioral responses to inflammation might be mediated by the effect of cytokines and other inflammatory signaling molecules on the interactions between neurons and the astrocytic cells (i.e., neuron-glia coupling) (Haroon et al. 2012; Miller et al. 2013). MRS-based technologies can be used to profile inflammation-induced changes in neuron-glia coupling. Haroon et al. (2014, 2015) demonstrated that induction of high-grade inflammation (following administration of interferon-alpha for the treatment of hepatitis C in nondepressed individuals) was associated with significant increases in glutamate concentrations in the dorsal ACC and left basal ganglia. The increased glutamate concentrations were in turn associated with depression, anhedonia, and reduced psychomotor activity, and these effects were greater in older individuals. In comparison, patients with chronic major

depressive disorder (MDD) associated with high inflammation demonstrated changes mostly in the basal ganglia regions characterized by increases in both glutamate and the astroglial marker myo-inositol ([Haroon et al. 2016](#)). Thus, MRS could be used to further study both the acute and the chronic impact of inflammation on mood-regulating and reward pathways.

## Structural Magnetic Resonance Imaging

As illustrated in [Table 7-2](#), MR technology has provided important information on structural abnormalities in various psychiatric disorders. Use of MR imaging-based methods in research on psychiatric disorders and their treatment is addressed in the chapters on individual disorders (see [Chapters 46-54](#) in this volume). Only a general introduction will be provided here. MR-based volumetric methods involve estimating volumes of cerebral structures using MR images. They may be divided into two types: automated (voxel-based morphometry [VBM]) and manual (region of interest [ROI]) methods. A detailed review of these methods is provided elsewhere ([Pearlson and Calhoun 2007](#)). Using volumetric studies of hippocampus in depression, [Sheline et al. \(2001\)](#) described a subtype of depression associated with hippocampal volume loss, memory impairment, and hippocampal loss of 5-HT<sub>2A</sub> receptors. The alteration of cerebral structure by medications has been reported as well. Using structural MRI methods, G.J. [Moore et al. \(2000\)](#) reported that lithium administration led to a 3% increase in the volume of gray matter within a period of about 4 weeks. Psychiatric disorders are clinically heterogeneous entities, and such structural MRI-based studies have helped us to characterize more specific pathological subtypes of depression. T2-weighted MRI studies have also been used to identify and rate subcortical hyperintensities, the increase of which is believed to result in late-life cerebrovascular disease and late-life depression ([Alexopoulos et al. 1997](#); [Kumar et al. 2002](#); [Parsey and Krishnan 1997](#)).

## Diffusion-Weighted and Diffusion Tensor Imaging

Diffusion-based imaging techniques, including diffusion-weighted imaging (DWI) and diffusion tensor imaging (DTI), obtain and use images of the microscopic diffusion properties of water as an indirect measure to estimate the microstructure integrity of all brain tissues, including white matter tracts ([Le Bihan 2003](#)). In free-form water, molecules have isotropic properties (i.e., they diffuse in multiple and often infinite directions). The extent of free diffusivity in all directions is known as *radial diffusivity*. Under restricted conditions in the white matter fiber tracts, the directional diffusion of water is highly restricted to a few vectors due to spatial limitations induced by the tightly packed nerve fibers, resulting in a phenomenon known as *anisotropic diffusion*, and the extent of this restricted or anisotropic diffusion is known as *fractional anisotropy*.

([Kubicki et al. 2007](#)). DTI-based studies have advanced the hypothesis that psychiatric disorders are characterized by altered connectivity (“disconnection syndromes”). Studies employing DTI methods have helped us understand how cerebral organization and connectivity might be altered in psychiatric disorders such as autism ([Alexander et al. 2007](#)), late-life depression (W.D. [Taylor et al. 2007](#)), and schizophrenia ([Nestor et al. 2007](#)). It should be borne in mind that the direction-dependent diffusion of water in white matter tracts corresponds to the predominant directional orientation of the fiber bundles (principal diffusion direction), and by using complex statistical modeling, it is possible to estimate these directions and to trace the fibers’ journey through the brain structure using a technique called probabilistic tractography ([Johansen-Berg et al. 2008](#)). Using this technique, it has also been possible to predict antidepressant treatment responses among patients with late-life depression ([Mettenburg et al. 2012](#)).

## Perfusion-Weighted MR Imaging and Arterial Spin Labeling

Traditionally, the assessment of activity in a tissue volume of interest was made using PET techniques involving exposure to radioactive tracers. Perfusion MRI techniques—which take advantage of the fact that the magnetization properties of arterial blood water are different from those of the underlying tissues—have been used to study increased resting blood flow (indexed by increased flow of arterial blood water). A subtype of perfusion MRI that uses magnetic labeling of increasing flow of arterial water proximal to the tissue volume of interest is known as arterial spin labeling (ASL) and has been used to study brain activity in disease states ([Detre et al. 2009, 2012](#)). Multiple studies have examined the effect of serotonin metabolism changes in depression. For example, it has been demonstrated that depressed patients who have the short allelic variant of the serotonin transporter (s/s group) show significantly increased resting CBF in the amygdala and decreased CBF in the ventromedial prefrontal cortex compared with patients who have the long allelic variant of the serotonin transporter (l/l group) ([Rao et al. 2007](#)). MDD patients subjected to acute tryptophan depletion showed increased resting-state habenular blood flow, and the increased resting-state amygdala blood flow (following acute tryptophan depletion) was associated with a more negative emotional bias score across both MDD and control patients ([Roiser et al. 2009](#)).

## Machine Learning

A major critique of modern neuroimaging studies is that they although they demonstrate statistically significant differences between study and control

groups, they are of limited clinical utility owing to low levels of sensitivity and specificity ([Orrù et al. 2012](#)). This is because conventional statistical analysis techniques aim to identify statistically significant group differences that depend on sample size and power. Machine learning enables the investigator to make sense of otherwise unstructured data by minimizing “noise” and differentiating noise from core data elements that explain most of the variance. For example, machine learning can be used to process imaging information from all brain voxels simultaneously (i.e., whole-brain model) to identify differences between the study and control groups. Thus, machine learning techniques enable us to identify minor but consistent alterations in widely distributed brain networks that can later be combined to profile brain-behavior relationships in neuropsychiatric disorders ([Borgwardt and Fusar-Poli 2012](#); [Davatzikos et al. 2005](#); [Orrù et al. 2012](#)).

## Multimodal Imaging Approaches

Another approach to overcoming the limitations of current neuroimaging study designs has been to use multimodal imaging techniques combined with advanced statistical analyses. For instance, a combined analysis of fMRI, structural MRI, and EEG data employing canonical correlation methods could be used to differentiate patients with schizophrenia from control subjects with a level of accuracy exceeding 90% certainty ([Sui et al. 2014](#)).

## Electroencephalography and Magnetoencephalography

---

The brain is an organ with a high level of intrinsic electrical activity. EEG and MEG are technologies that enable the recording of this electrical activity of the brain using scalp electrodes. These techniques are believed to represent brain activity in real time, and with a higher temporal resolution (~ msec) than PET or fMRI. The electrical activity recorded is generated by the postsynaptic potentials of the neurons and hence represents a direct indication of neural activity. The EEG detects the electrical potential of the field, while MEG detects the magnetic component. EEG uses relatively simple equipment, basically a multielectrode helmet, an amplifying and filtering device, and a computer ([Ebner et al. 1999](#)). A minimum of 32 scalp electrodes are needed to localize the sources of the recorded potential EEG, but high-density arrays of 128 or 256 electrodes are employed increasingly in research. MEG, by contrast, employs cutting-edge technology ([Ioannides 2006](#)), because the detection of a magnetic field intensity as weak as the one produced by the brain (~20,000 billion times weaker than the intensity of the Earth’s magnetic field) requires the use of superconducting

coil units based on superconducting quantum interference device (SQUID) technology. These units need to be specially cooled to a temperature near absolute zero. To avoid the intrusion of electromagnetic interference from the environment, the recording takes place in a room that has been appropriately shielded. MEG commonly employs arrays of 100–300 detectors.

Given the high temporal resolution of MEG and EEG, these techniques are used to study simultaneous (time-locked) neural discharges occurring in distant or contiguous groups of neurons, often referred to as “synchronous neural activity” (Tononi and Edelman 1998; Varela et al. 2001). These synchronous neural discharges are seen in both pathological situations (such as seizure discharges) and normal physiological situations (such as during development of function neural circuits). The high temporal resolution also enables measurement of neural response to sensory (somatosensory) or cognitive stimuli delivered from outside, and this process, known as the study of *evoked* or *event-related potentials*, has enabled considerable progress in understanding the pathophysiology of several neurological and psychiatric disorders. The temporal sequence of the neural responses following delivery of the stimulus (known as “time series”) is measured sequentially and averaged to generate a waveform. By combining all waveforms from all detectors, one can develop a surface map of the beginning, middle, and end of the neural response to a given stimulus.

In spite of such advances, there are some barriers to using EEG or MEG in routine clinical contexts. First, these techniques provide limited spatial resolution, given that the recorded electrical signals are averaged over extended regions of the brain. Attempts have been made to overcome this limitation through technical and mathematical means, such as the use of “dense array” (128–256 electrodes) coils to obtain multiple electrical potentials, which can then be combined using complex mathematical models to yield anatomically relevant data. Second, EEG and MEG are essentially surface techniques; because the intensity of the electromagnetic field decreases rapidly with distance, detection of neural signals is restricted to the sources closest to the detectors—that is, the neocortex. The activity of subcortical regions is very difficult to detect.

Despite these limitations, studies using EEG and related technology of evoked potentials have made significant contributions to our understanding of the pathophysiology of neurological and psychiatric disorders. Examples of such studies include the following:

1. Abnormalities in power spectral analysis of the resting-state EEG and study of evoked potentials in response to auditory stimuli have been consistently associated with core cognitive and neurochemical deficits in patients with schizophrenia and might lead to more effective subtyping of the disorder and delivery of more targeted and personalized care (Ford and Mathalon 2005; Turetsky et al. 1998).

2. Studies using dense-array EEG suggest that moderate depression may sensitize limbic networks to respond more strongly to aversive events than to positive events ([Tucker et al. 2003](#)).
3. EEG has been combined with other functional imaging techniques to yield highly specific temporal and spatial information, which could then be used to study deficits in neural systems and reward anticipation across multiple diagnostic entities ([Gorka et al. 2015](#)).
4. Some authors have recommended the use of EEG technologies in conjunction with fMRI to study analgesia and pain management ([Wise and Tracey 2006](#)).
5. Combined PET and EEG technologies using a source localization technique have identified disruption of frontocingulate connectivity among patients with depression ([Pizzagalli et al. 2003](#)). Studies such as these provide critical information that can complement and enhance our understanding of functional imaging approaches.
6. A series of papers have reported consistent evidence showing that quantitative EEG (qEEG) changes are predictive not only of antidepressant response but also of placebo response and might also help identify specific subtypes who will benefit from neuroplasticity-promoting treatments such as transcranial magnetic stimulation ([Leuchter et al. 2015](#)).
7. EEG-derived brain rhythm patterns have been proposed as putative biomarkers for objectively evaluating neuromodulation success and for guiding deep brain stimulation or other target-based neuromodulation strategies for patients with treatment-resistant depression ([Broadway et al. 2012](#)).

## Novel Insights From Brain Imaging in Applied Clinical Psychopharmacology

---

### Identifying Individuals at Risk of Developing Psychopathology

#### MAO-PET Labeling Studies

[Sacher et al. \(2012\)](#) used  $^{11}\text{C}$ -harmine PET scanning technology to measure the effect of changes in monoamine oxidase A (MAO-A) binding in brain regions implicated in affective and neurodegenerative disease. They showed that elevated activity of MAO in the ACC and prefrontal cortical area not only was associated with increases in depressive symptoms but also predicted the development of postpartum depression. This study demonstrates how receptor-labeling PET-ligand studies can provide novel therapeutic targets for new drug development and also inform the pathophysiology of depressive conditions. More

importantly, early identification of high-risk individuals might usher in an era of prophylactic medication therapy.

## **Machine-Learning Approach to Profiling Risk of Bipolar Disorder**

Neuroimaging findings from illness-based cohorts are often contaminated by chronicity effects of illness duration, medication exposure, and medical comorbidities ([Hajek et al. 2015](#)). A highly relevant approach in this regard might be to study patterns of neuroimaging change among genetically high-risk individuals, such as biological relatives of probands with a highly heritable disorder such as bipolar disorder, and to compare these high-risk individuals with a population of healthy control subjects. These data can then be analyzed by specialized pattern-recognition software such as support vector machines ([Orrù et al. 2012](#)) to identify patterns that differentiate high-risk individuals from healthy controls. Machine learning has recently been used to identify individuals at high genetic risk for bipolar disorder based on brain structure by comparing offspring of parents with bipolar disorder with an age- and sex-matched control group. Much to the surprise of the investigators, the brain changes, which significantly contributed to the between-group discrimination, included white matter of inferior/middle regions of frontal and temporal gyri and precuneus and not any of the gray matter regions included in the study ([Hajek et al. 2015](#)).

## **Neurochemical Targeting in Antipsychotic Treatment**

### **Mechanisms of Dopamine System Hyperresponsiveness in Schizophrenia**

It has long been known that patients diagnosed with schizophrenia have an exaggerated dopamine response to amphetamine challenge. [Laruelle et al. \(1995\)](#) conducted a landmark study in which they used SPECT to profile intrasynaptic dopamine release in human striatum following dextroamphetamine sulfate (D-amphetamine) challenge testing. Using the D<sub>2</sub> receptor-labeling radiotracer [<sup>123</sup>I]-iodobenzamide ([<sup>123</sup>I]IBZM), they demonstrated a decrease in D<sub>2</sub> receptor availability resulting from exaggerated release of dopamine (which occupied the D<sub>2</sub> receptors in response to amphetamine challenge) in the schizophrenic brains compared with healthy brains ([Laruelle et al. 1995](#)). This study was one of the very first to demonstrate the power of modern neuroimaging to shed light on neurochemical processes that mediate drug action.

## Discrimination of Biological Changes Mediating Effects and Side Effects of Antipsychotic Medication

Antipsychotic pharmacotherapy is heavily based on the premise that a correction of the exaggerated dopaminergic response might overstimulate D<sub>2</sub> receptors. However, excessive and near-total blockade of the D<sub>2</sub> receptors can lead to unwanted extrapyramidal side effects (EPS) and motor symptoms. Using a series of innovative PET ligand-based imaging paradigms, Kapur and colleagues ([Ginovart and Kapur 2012](#); [Kapur and Seeman 2001](#)) explored the question of whether the thresholds for clinical response and for EPS could be separated in terms of differential D<sub>2</sub> occupancy, measured via the PET-based D<sub>2</sub> binding ligand <sup>11</sup>C-raclopride following administration of haloperidol. They found that D<sub>2</sub> occupancy at a threshold of 65% significantly predicted clinical response, whereas D<sub>2</sub> occupancy above 78% produced EPS, and D<sub>2</sub> occupancy above 72% produced significant prolactin elevation. Thus, even with a relatively typical antipsychotic such as haloperidol, it is possible, although not clinically feasible, to obtain an antipsychotic effect without causing EPS just by optimizing D<sub>2</sub> occupancy. The authors later extended this observation to show that whereas even atypical antipsychotic agents with a low propensity to cause EPS, such as quetiapine and clozapine, achieved D<sub>2</sub> binding rates of 60% within 2 hours following administration (which might explain their antipsychotic efficacy), D<sub>2</sub> binding rates declined to less than 20% after 12 hours in the case of quetiapine and to 26% after 24 hours in the case of clozapine (which might underlie these agents' relative lack of EPS). The atypical antipsychotics risperidone and olanzapine achieve robust antipsychotic activity only at dosages producing D<sub>2</sub> receptor occupancy of 65% or greater, which is similar to the action of haloperidol ([Ginovart and Kapur 2012](#); [Kapur and Seeman 2001](#)).

## Profiling to Guide Treatment Selection

Identifying patients who will be ideal candidates for the manifold treatment options for major depressive disorder has been an ongoing challenge ([Alhajji and Nemeroff 2015](#)). Neuroimaging profiles have been proposed as biomarkers that could subtype and identify patients for specific therapies. Accordingly, insula hypometabolism (as indexed by <sup>18</sup>FDG uptake) was shown to be associated with achievement of remission with cognitive-behavioral therapy and poor response to escitalopram, while insula hypermetabolism was associated with achievement of remission with escitalopram and poor response to cognitive-behavioral therapy ([McGrath et al. 2013](#)).

## Subtyping of Clinical Syndromes

Not every patient with schizophrenia responds to D<sub>2</sub>-blocking antipsychotic medications. Using [<sup>18</sup>F] DOPA PET to label presynaptic dopamine synthesis, [Demjaha et al. \(2012\)](#) demonstrated that patients who responded to antipsychotic treatment showed significantly higher [<sup>18</sup>F] DOPA uptake in the striatum compared with patients who did not respond to D<sub>2</sub>-blocking agents. This important study points to the possibility that neuroimaging techniques might be used to profile antipsychotic-responsive versus nonresponsive schizophrenic patient subgroups.

## Elucidating Mechanisms of Action of Novel and Older Treatments

### Neuroimaging Studies of the Mechanism of Ketamine's Antidepressant Effects

Ketamine is a novel antidepressant with both a novel mechanism of action and a rapid antidepressant effect seen within hours of administration (as opposed to a time lapse of weeks). The precise mechanisms underlying its rapid antidepressant effects are being explored using novel neuroimaging techniques. Studies have consistently shown a decrease in pretreatment resting ACC activity and decreased engagement of pregenual ACC in response to cognitive challenge induced by a working-memory paradigm ([Salvadore et al. 2009, 2010](#)). In addition, treatment-resistant depression was associated with decreased neural responses in the right caudate to faces showing positive emotional expression—a change that was reversed following antidepressant response to ketamine ([Murrough et al. 2015](#)). Rapid antidepressant response to ketamine was also associated with decreases in amygdalar activity ([Salvadore et al. 2010](#)). Synaptic potentiation has been proposed as a mechanism underlying chronic antidepressant treatment response, and it is clear that repeated administration of ketamine induces synaptic proteins and enhances synaptic plasticity. A temporal dissociation between acute changes in cortical excitability (measured using MEG) and clinical antidepressant response led to the conclusion that ketamine's antidepressant effects might be mediated by non-*N*-methyl-D-aspartate (NMDA)-induced synaptic plasticity mechanisms ([Cornwell et al. 2012](#)). MRS measurements of glutamate response to ketamine administration among depressed and nondepressed human subjects have shown varied results, with some studies showing no changes ([Forbes et al. 2009](#); [Stone et al. 2012](#); [M.J. Taylor et al. 2012](#); [Valentine et al. 2011](#)) and others showing increases in glutamate concentrations ([Milak et al. 2016](#); [Rowland et al. 2005](#); [Salvadore et al. 2012](#)). Nevertheless, MRS measurements obtained within a short time window of 26 minutes following ketamine administration demonstrated greater increases in glutamate than were seen in scans obtained after longer wait times ([Milak et al. 2016](#)).

## Acute and Delayed Effects of Neuromodulation Using Deep Brain Stimulation

Neuromodulation treatments remain the last few options available for treatment-resistant depression and include commercially available approaches such as ECT, transcranial magnetic stimulation (TMS), and vagus nerve stimulation (VNS) as well as experimentally available modalities such as transcranial direct current stimulation (tDCS), magnetic seizure therapy, cortical brain stimulation, and DBS. A detailed description of network changes during neuromodulation treatments is beyond the scope of this chapter, and readers are referred to authoritative reviews on the topic published elsewhere ([Smart et al. 2015](#)). Multimodality imaging techniques have been used to guide and inform target selection for neuromodulation treatments based on DBS. Preoperatively acquired diffusion imaging for connectivity-based cortical mapping in combination with postoperative computed tomography could improve neurosurgical targeting and has been used to delineate adaptive changes in white matter tracts and modulation of neural activity in response to the immediate and delayed effects of DBS. Using these cortical mapping techniques, [Johansen-Berg et al. \(2008\)](#) demonstrated that the acute antidepressant effects of DBS were mediated by its effect on a network involving the subgenual ACC region (BA 25), with strongest connections to nucleus accumbens, amygdala, hypothalamus, and orbitofrontal cortex. [Choi et al. \(2015\)](#) used structural connectivity analysis to show that the best intraoperative response to DBS consisted of both interoceptive and exteroceptive changes involving contacts connected to the bilateral ventromedial frontal cortex (via forceps minor and left uncinate fasciculus) and the cingulate cortex (via left cingulum bundle). Later studies at 6 months and 2 years showed that response to DBS not only engaged the above regions but also recruited additional regions ([Crowell et al. 2015](#)). Specifically, all DBS responders showed engagement by subgenual ACC of the same bilateral pathways from their activation volumes in subgenual ACC to 1) medial frontal cortex via forceps minor and uncinate fasciculus, 2) rostral and dorsal cingulate cortex via the cingulum bundle, and 3) subcortical nuclei ([Riva-Posse et al. 2014](#)). Similar strategies are also guiding refined target selection for noninvasive neuromodulation techniques such as repetitive TMS ([Fox et al. 2014](#)).

## Improved Understanding of Mechanism of Action of Older Medications

While multiple newer and faster-acting treatments have become available to treat depression, older agents such as SSRIs continue to be widely useful. Negative cognitive bias is a vulnerability marker for depression, and its neural footprints have been mapped with fMRI indices such as exaggerated amygdalar response to fearful faces. Catherine Harmer and colleagues used a double-blind, placebo-controlled pharmacological fMRI paradigm to demonstrate that a single

dose of intravenous citalopram resulted in significantly greater reductions in amygdalar responses to fearful facial expressions compared with placebo (Murphy et al. 2009). In a subsequent study, the same group demonstrated that oral citalopram given at 10 mg/day for 7 days resulted in similar reductions in exaggerated amygdalar response to negative emotional stimuli, which predicted clinical improvement in depressed mood (Godlewska et al. 2012).

## Conclusion

---

Contemporary brain-imaging methods provide a variety of strategies to probe structural, functional, and chemical abnormalities in specific neural circuits relevant to psychiatric illness. Such studies are having a considerable impact on our conceptualization of these disorders, with potential impacts on diagnosis (Mayberg 2003a), clinical management (monitoring occupancy or PIB changes with treatment [Klunk et al. 2004]), and novel treatment development (Mayberg 2009). Brain-imaging studies in psychopharmacology can be categorized both by the scanning technology employed (e.g., MRI, PET, EEG) and by the type of measurement obtained (e.g., activation, resting state, behavioral, biochemical, receptor mapping). Receptor-mapping studies have clearly added to our ability to understand mechanisms of action of psychopharmacological agents and their side-effect profiles. Activation studies, which indirectly measure neuronal activity vis-à-vis changes in CBF, have become widely used with fMRI technology, providing new insights into behaviorally specific subcircuits. Structural MRI studies have also begun to yield considerable data, enabling a better understanding of how the disease processes are regionally localized, where to target for functional imaging, and where to obtain specimens for postmortem histopathological analysis. Multimodal imaging through a combination of fMRI, PET, structural MRI, MRS, and electromagnetic measurement (EEG, MEG) offers the promise of identifying both neuronal and chemical changes related to brain function.

## CHAPTER 8

# Monoamine Oxidase Inhibitors

K. Ranga Rama Krishnan, M.D.

### History and Discovery

---

Monoamine oxidase inhibitors (MAOIs) were first identified as effective antidepressants in the late 1950s. An early report suggested that iproniazid, an antitubercular agent, had mood-elevating properties in patients who had been treated for tuberculosis ([Bloch et al. 1954](#)). Following these observations, two studies confirmed that iproniazid did indeed have antidepressant properties ([Crane 1957](#); [Kline 1958](#)). [Zeller \(1963\)](#) showed that iproniazid caused potent inhibition of monoamine oxidase (MAO) enzymes both in vivo and in vitro in the brain. He also reported that the medication reversed some of the actions of reserpine. Because reserpine produced significant depression as a side effect, it was suggested that iproniazid might have mood-elevating properties.

The use of iproniazid soon fell into disfavor because of its significant hepatotoxicity. Other MAOIs, both hydrazine derivatives (e.g., isocarboxazid, phenylhydrazine) and nonhydrazine derivatives (e.g., tranylcypromine), were introduced. These MAOIs were not specific for any subtype of MAO enzyme, and they were irreversible inhibitors of MAO (see next section, “Monoamine Oxidase”). Their use has been rather limited because hypertensive crisis by the MAOIs may occur in some patients from potentiation of the pressor effects of amines (such as tyramine) in food ([Blackwell et al. 1967](#)).

In more recent years, there has been a resurgence of interest in the development of new MAOIs—that is, in development of MAOIs that are more selective for specific subtypes of MAO enzyme and that are reversible in nature. Reversible monoamine oxidase A (MAO-A) inhibitors, such as moclobemide, have been introduced in Europe but are not available in the United States. Newer MAOIs, such as selegiline, a monoamine oxidase B (MAO-B) inhibitor, have been introduced. [Table 8-1](#) classifies the MAOIs by structure, selectivity, and reversibility.

### A and B Isoenzymes

MAO is widely distributed in mammals. Two isoenzymes, MAO-A and MAO-B, are of special interest ([Cesura](#) and

[Pletscher 1992](#)). Both are present in the central nervous system (CNS) and in some peripheral organs. For example, MAO-A is present in the liver, heart, and pancreas, and MAO-B is present in the liver, posterior pituitary, renal tubules, and endocrine pancreas ([Saura et al. 1992](#)). Both MAO-A and MAO-B are present in discrete cell populations within the CNS. MAO-A is present in both dopamine (DA) and norepinephrine (NE) neurons, whereas MAO-B is present to a greater extent in serotonin (5-HT)-containing neurons. Both are also present in nonaminergic neurons in various subcortical regions of the brain. Glial cells also express MAO-A and MAO-B ([Cesura and Pletscher 1992](#)).

The physiological functions of these two isoenzymes have not been fully elucidated. The main substrates for MAO-A are epinephrine, NE, and 5-HT. The main substrates for MAO-B are phenylethylamine, phenylethanolamine, tyramine, and benzylamine. DA and tryptamine are metabolized by both isoenzymes. The localization of the MAO subtypes does not fully correspond to the neurons containing the substrates. The reason for this discrepancy is unknown. The occurrence of the MAO-B form in 5-HT neurons may actually protect these neurons from amines (other than 5-HT) that could be toxic to them ([Cesura and Pletscher 1992](#)).

The primary structures of MAO-A and MAO-B have been fully described. MAO-A has 527 amino acids, and MAO-B has 520 amino acids. About 70% of the amino acid sequence of the two forms is homologous. The genes for both isoenzymes are located on the short arm of the human X chromosome. MAO-A and MAO-B are linked and have been located in the XP11.23-P11 and XP22.1 regions, respectively. The genes span about 70 kilobases (kb) and consist of about 15 exons and 14 introns. MAO-A has two messenger RNA (mRNA) transcripts of 2.1 and 5.0 kb in length. MAO-B has a 3-kb

mRNA single transcript ([Cesura and Pletscher 1992](#)). A rare inherited disorder, Norrie's disease, is characterized by deletion of both genes; patients with this disorder have very severe mental retardation and blindness. Another rare inherited disorder is Brunner syndrome, caused by a mutation in the MAO-A gene. It is characterized by impulsive aggressiveness and mild mental retardation ([Brunner et al. 1993](#)).

The subunit composition of MAO is unknown. The enzyme is primarily found in the outer mitochondrial membrane; flavin adenine dinucleotide is a cofactor for both MAO-A and MAO-B.

Because the cofactor domain is the same for both of the MAO isoenzymes, the structural differences responsible for substrate specificity are believed to lie in regions of the protein that bind to the hydrophobic moiety of the substrate. Although DA is considered to be a mixed substrate for both MAO-A and MAO-B, the breakdown of DA in the striatal regions of the brain is preferentially by MAO-B. In other regions, MAO-A may be more important. There may be regional differences as to which isoenzyme is responsible for the metabolism of other biogenic amines that are substrates for both forms of MAO ([Cesura and Pletscher 1992](#)).

## Enzyme Kinetics

The enzyme kinetics of MAO-A have not been well studied. The enzyme kinetics for MAO-B, for which more information is available, depend on the nature of the substrate. Some substrates (e.g., tyramine) go through ping-pong mechanisms characterized by oxidation of the amine to the imine form, which is subsequently released from the reduced enzyme before reoxidation occurs. Other substrates (e.g.,

benzylamine) involve formation of a tertiary complex with the enzyme and oxygen ([Husain et al. 1982](#); [Pearce and Roth 1985](#); [Ramsay and Singer 1991](#)).

## Positron Emission Tomographic Studies of MAO-A in Psychiatric Disorders

[<sup>11</sup>C]Harmane is a selective reversible positron emission tomography (PET) radiotracer with high brain uptake that binds with high affinity to MAO-A. A study using this tracer reported highly significant elevations in brain MAO-A binding during episodes of major depressive disorder that persisted even after selective serotonin reuptake inhibitor (SSRI) treatment ([Meyer et al. 2009](#)). Interestingly, subjects with higher MAO-A levels had a higher rate of major depressive episode recurrence ([Meyer et al. 2009](#)).

---

## Mechanism of Action

---

The target function of MAOIs is regulation of the monoamine content within the nervous system. Because MAO is bound to the outer surface of the plasma membrane of the mitochondria, in neurons MAO is unable to deaminate amines that are present inside stored vesicles and can metabolize only amines that are present in the cytoplasm. As a result, MAO maintains a low cytoplasmic concentration of amines within the cells. Inhibition of neuronal MAO produces an increase in the amine content in the cytoplasm. Initially, it was believed that the therapeutic action of MAOIs was a

result of this amine accumulation (Finberg and Youdim 1984; Murphy et al. 1984, 1987). More recently, it has been suggested that secondary adaptive mechanisms may be important for the antidepressant action of these agents.

After several weeks of treatment, MAOIs produce effects such as a reduction in the number of  $\beta$ -adrenoceptors,  $\alpha_1$ - and  $\alpha_2$ -adrenoreceptors, and serotonin type 1 (5-HT<sub>1</sub>) and serotonin type 2 (5-HT<sub>2</sub>) receptors. These changes are similar to those produced by the chronic use of tricyclic antidepressants (TCAs) and other antidepressant treatment (DaPrada et al. 1984, 1989).

MAOIs can be subdivided on the basis of not only the particular type of enzyme inhibition but also the type of inhibition they produce (reversible or irreversible). The reversible MAOIs are basically chemically inert substrate analogs. MAOIs are recognized as substrates by the enzyme and are converted into intermediates by the normal mechanism. These converted compounds react to the inactive site of the enzyme and form a stable bound enzyme. This effect occurs gradually, and there is usually a correlation between the plasma concentration of the reversible inhibitors and pharmacological action.

---

## Pharmacological Profile

---

The classic MAOIs inhibit both forms of the enzyme and are divided into two main subtypes: hydrazine and nonhydrazine derivatives (Figure 8-1). The hydrazine derivatives, two of which are currently available (phenelzine and isocarboxazid), are related to iproniazid. One nonhydrazine derivative, tranylcypromine, is commercially available.

### Irreversible nonselective (classic) MAOIs

### Irreversible selective MAOI

### Reversible MAO-A inhibitor

**FIGURE 8-1.** Chemical structures of monoamine oxidase inhibitors (MAOIs).

Among the selective MAOIs, clorgyline (which was never marketed in the United States) is an example of an irreversible inhibitor of MAO-A, whereas selegiline is an irreversible inhibitor of MAO-B. Moclobemide is the only reversible inhibitor of MAO-A on the market (available in the United Kingdom and Australia, but not in the United States).

Three classic MAOIs (i.e., phenelzine, isocarboxazid, and tranylcpromine) are of clinical interest. Clinicians must recognize that these drugs not only inhibit MAO but also exert other actions that may be clinically relevant. Thus, these compounds can block MAO uptake—tranylcpromine more than isocarboxazid or phenelzine. In addition, because

tranylcypromine is structurally similar to amphetamine, it is believed to exert stimulant-like actions in the brain. Many issues are common to all three of these MAOIs.

## **Major Depressive Disorder and Atypical Depression**

Many studies have examined the efficacy of the irreversible MAOIs in the treatment of different types of depression. MAOIs have been effective in the treatment of major depressive disorder and atypical depression (defined as depression with anxiety or chronic pain, reversed vegetative symptoms, and rejection sensitivity [[Quitkin et al. 1990](#)]) ([Davidson et al. 1987a](#); [Himmelhoch et al. 1982, 1991](#); [Johnstone 1975](#); [Johnstone and Marsh 1973](#); [McGrath et al. 1986](#); [Paykel et al. 1982](#); [Quitkin et al. 1979, 1990, 1991](#); [Rowan et al. 1981](#); [Thase et al. 1992](#); [Vallejo et al. 1987](#); [White et al. 1984](#); [Zisook et al. 1985](#)). Although early studies of relatively low-dosage regimens suggested that the efficacy of MAOIs was lower than that of TCAs, more recent studies have documented that their efficacy is comparable.

[Quitkin et al. \(1979, 1991\)](#) reviewed both phenelzine and tranylcypromine studies in patients with either atypical depression or melancholic depression. The authors reported that phenelzine appeared to be effective for the treatment of atypical depression.

Relatively few studies have investigated MAOIs in patients with endogenous depression (i.e., depression without known precipitating factors). From the limited number of patient

studies, it is difficult to conclude that phenelzine is effective in the treatment of these patients. In addition, very few well-controlled studies have compared tranylcypromine with placebo. Three of the four studies that compared tranylcypromine with placebo showed that tranylcypromine was more effective ([Himmelhoch et al. 1982](#); [Moises and Beckmann 1981](#); [White et al. 1984](#)). In one study, a nonsignificant trend was found favoring tranylcypromine ([Nolen 1989](#)). Studies have also documented the efficacy of tranylcypromine in treating anergic depression and, at high doses, treatment-resistant depression ([Himmelhoch et al. 1982, 1991](#); [Thase et al. 1992](#); [White et al. 1984](#)). In the Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) study, patients who had failed to respond to at least three treatment options were randomly assigned to tranylcypromine or a combination of venlafaxine and mirtazapine. Remission rates were modest for both the tranylcypromine group and the extended-release venlafaxine plus mirtazapine group, and the rates were not statistically different between groups ([McGrath et al. 2006](#)).

The heterogeneity of acetylation rate may account for some of the variance in response to phenelzine ([Johnstone 1975](#); [Johnstone and Marsh 1973](#); [Paykel et al. 1982](#); [Rowan et al. 1981](#)). One-half of the patients in a given population are often slow acetylators. An initial study by [Johnstone and Marsh \(1973\)](#) suggested that slow acetylators improve more with phenelzine than do fast acetylators. Other groups have been unable to confirm the relation between acetylation, acetylator type, and response to MAOIs.

Early studies suggested that irreversible MAOIs are particularly effective in patients who have atypical depression. The concept of atypical depression remains controversial and has not been completely validated. In

general, patients with atypical depression have an earlier age at onset than do patients with melancholic depression, and the prevalence of dysthymia, alcohol abuse, sociopathy, and atypical depression is increased in the relatives of patients with atypical depression. The best differentiating criterion appears to be that phenelzine and other irreversible MAOIs are more effective than TCAs in treating these patients ([Cesura and Pletscher 1992](#); [Quitkin et al. 1990](#); [Zisook et al. 1985](#)). A meta-review noted evidence that MAOIs are superior to TCAs, but not SSRIs, in treating atypical depression ([Cipriani et al. 2007](#)).

Some studies have also suggested that MAOIs are effective in treating major depressive disorder and melancholic depression ([Davidson et al. 1987a](#); [McGrath et al. 1986](#); [Vallejo et al. 1987](#)). In a Cochrane review, [Lima and Moncrieff \(2000\)](#) noted that MAOIs were comparable in efficacy to other classes of antidepressants in treating dysthymia.

## **Panic Disorder**

Both single- and double-blind studies have demonstrated the efficacy of phenelzine and iproniazid in treating panic disorder ([Lydiard et al. 1989](#); [Quitkin et al. 1990](#); [Tyrer et al. 1973](#)). About 50%–60% of patients with panic disorder respond to irreversible MAOIs. In the early stages of treatment, patients may have a worsening of symptoms. This is reduced in clinical practice by combining the MAOI with a benzodiazepine for the initial phase of the study. It has been suggested that in addition to having an antipanic effect, phenelzine has an antiphobic action ([Kelly et al. 1971](#)). The time course of effect and the dose used are similar to those for major depressive disorder.

## **Social Phobia**

[Liebowitz et al. \(1992\)](#) reported that phenelzine is effective in treating social phobia. In an open-label study, [Versiani et al. \(1988\)](#) suggested that tranylcypromine is effective. [Versiani et al. \(1992\)](#) also demonstrated the efficacy of the reversible MAOI moclobemide in a double-blind study. About 50% of patients respond to MAOIs, and the onset of response is gradual (usually about 2–3 weeks) ([Liebowitz et al. 1992](#)).

A Cochrane review of pharmacotherapy for social phobia noted that whereas classic irreversible MAOIs were comparable in efficacy to SSRIs, reversible MAOIs were less efficacious ([Stein et al. 2004](#)).

## **Obsessive-Compulsive Disorder**

Although initial case reports suggested that irreversible MAOIs may be effective in treating obsessive-compulsive disorder ([Jenike 1981](#)), no double-blind studies conducted have indicated efficacy ([Jenike et al. 1997](#)).

## **Posttraumatic Stress Disorder**

The classic MAOI phenelzine has been proven effective for the treatment of posttraumatic stress disorder (PTSD) in single-blind trials ([Davidson et al. 1987b](#)) and a double-blind crossover trial ([Kosten et al. 1991](#)).

## **Generalized Anxiety Disorder**

MAOIs are not usually used to treat generalized anxiety disorder because the risk-benefit ratio favors the use of SSRIs, azapirones, or benzodiazepines. When they are used, MAOIs are used primarily for treating treatment-resistant generalized anxiety disorder.

## **Bulimia Nervosa**

Both phenelzine and isocarboxazid have been shown to be effective in treating some symptoms of bulimia nervosa ([Kennedy et al. 1988](#); [McElroy et al. 1989](#); [Walsh et al. 1985, 1987](#)).

## **Premenstrual Dysphoria**

Preliminary studies and clinical experience suggest that MAOIs may be effective in the treatment of premenstrual dysphoria ([Glick et al. 1991](#)).

## **Chronic Pain**

MAOIs are believed to be effective in the treatment of atypical facial pain and other chronic pain syndromes. However, only limited data on these conditions are available.

## **Neurological Diseases**

The classic MAOIs have not been found to be effective for treating neurological disorders such as Parkinson's disease and Alzheimer's dementia. However, the MAO-B inhibitor selegiline has been shown to be effective in slowing the progression of Parkinson's disease ([Cesura and Pletscher 1992](#)), although the mechanism underlying this effect is unknown.

# **Side Effects and Toxicology**

The side effects of irreversible MAOIs are generally not more severe or frequent than those of other antidepressants ([Zisook 1984](#)). The most frequent side effects include dizziness, headache, dry mouth, insomnia, constipation, blurred vision, nausea, peripheral edema, forgetfulness, fainting spells, trauma, urinary hesitancy, weakness, and myoclonic jerks. Loss of weight and appetite may occur with

isocarboxazid use ([Davidson and Turnbull 1982](#)). Hepatotoxicity is rare with the currently available irreversible MAOIs, unlike with iproniazid. However, liver enzymes, such as aspartate transaminase and alanine transaminase, are elevated in 3%–5% of patients. Liver function tests must be done when patients have symptoms such as malaise, jaundice, and excessive fatigue.

Some side effects of irreversible MAOIs first emerge during maintenance treatment ([Evans et al. 1982](#)). These side effects include weight gain (which occurs in almost one-half of patients), edema, muscle cramps, carbohydrate craving, sexual dysfunction (usually anorgasmia), pyridoxine deficiency ([Goodheart et al. 1991](#)), hypoglycemia, hypomania, urinary retention, and disorientation. Peripheral neuropathy ([Goodheart et al. 1991](#)) and speech blockage ([Goldstein and Goldberg 1986](#)) are rare side effects of irreversible MAOIs. Weight gain is more of a problem with hydrazine compounds, such as phenelzine, than with tranylcypromine. Therefore, weight gain that is caused by hydrazine derivatives is an indication to switch to tranylcypromine. Edema is also more common with phenelzine than with tranylcypromine.

The management of some of these side effects can be difficult. Orthostatic hypotension is common with irreversible MAOIs. Addition of salt and salt-retaining steroids such as fludrocortisone (9- $\alpha$ -fluorohydrocortisone) is sometimes effective in treating orthostatic hypotension. Elastic support stockings are also helpful. Small amounts of coffee or tea taken during the day also keep the blood pressure elevated. The dose of fluorohydrocortisone should be adjusted carefully, because in elderly patients it could provoke cardiac failure resulting from fluid retention.

Sexual dysfunction that occurs with irreversible MAOIs is also difficult to treat. Common problems include anorgasmia, decreased libido, impotence, and delayed ejaculation ([Harrison et al. 1985](#); [Jacobson 1987](#)). Cyproheptadine is sometimes effective in treating sexual dysfunction such as anorgasmia. Bethanechol may also be effective in some patients.

Insomnia occasionally occurs as an intermediate or late side effect of irreversible MAOIs. Changing the time of administration does not seem to help much, although dosage reduction may be helpful. Adding trazodone at bedtime is effective, but this should be done with caution. Myoclonic jerks, peripheral neuropathy, and paresthesias, when present, are also difficult to treat. When a patient has paresthesia, the clinician should evaluate for peripheral neuropathy and pyridoxine deficiency. In general, patients taking irreversible MAOIs should also receive concomitant pyridoxine therapy. When myoclonic jerks occur, patients can be treated with cyproheptadine.

Irreversible MAOIs also have the potential to suppress anginal pain; therefore, coronary artery disease could be overlooked or underestimated.

Patients with hyperthyroidism are more sensitive to irreversible MAOIs because of their overall sensitivity to pressor amines. Irreversible MAOIs can also worsen hypoglycemia in patients taking hypoglycemic agents such as insulin.

## Dietary Interactions

After the introduction of irreversible MAOIs, several reports of severe headaches in patients who were taking these compounds were published ("[Cheese and Tranylcypromine](#)")

1970; Cronin 1965; Hedberg et al. 1966; Simpson and Gratz 1992). These headaches were caused by a drug-food interaction. The risk of such an interaction is highest for tranylcypromine and lower for phenelzine, provided that the dose of the latter remains low. However, the clinician must keep in mind that this interaction can occur even at low doses with any of the classic MAOIs. The interaction of irreversible MAOIs with food has been attributed to increased tyramine levels. Tyramine, which has a pressor action, is present in a number of foodstuffs. It is normally broken down by the MAO enzymes and has both direct and indirect sympathomimetic actions. It has been suggested that the potentiation of tyramine by an MAOI may be secondary to increased release of NE rather than to the MAOI. Adrenaline would increase the indirect sympathetic activity of tyramine. The spontaneous occurrence of hypertensive crises in a few patients lends support to this hypothesis (O'Brien et al. 1992; Zajecka and Fawcett 1991).

The tyramine effect of food is potentiated by MAOIs 10- to 20-fold. A mild tyramine interaction occurs with about 6 mg of tyramine; 10 mg can produce a moderate episode, and 25 mg can produce a severe episode that is characterized by hypertension, occipital headache, palpitations, nausea, vomiting, apprehension, occasional chills, sweating, and restlessness. On examination, neck stiffness, pallor, mild pyrexia, dilated pupils, and motor agitation may be seen. The reaction usually develops within 20-60 minutes after ingestion of food. Occasionally, the reaction can be very severe and may lead to alteration of consciousness, hyperpyrexia, cerebral hemorrhage, and death. Death is exceedingly rare (Cooper 1989).

The classic treatment of the hypertensive reaction is phentolamine (5 mg) administered intravenously (Youdim et

al. 1987; Zisook 1984). Nifedipine, a calcium channel blocker, has been shown to be effective (Stumpf 1988). Nifedipine has an onset of action of about 5 minutes, and it lasts approximately 3–5 hours; in fact, some clinicians have suggested that patients should carry nifedipine with them for immediate use in the event of a hypertensive crisis.

Because of the drug interaction of the classic MAOIs with food, clinicians usually make several dietary recommendations (Table 8-3). These recommendations are quite varied.

---

**TABLE 8-3. Food restrictions for monoamine oxidase inhibitors (MAOIs)**

---

<b>To be avoided</b>	<b>To be used in moderation</b>
Cheese (except cream cheese and cottage cheese)	Coffee
Overripe (aged) fruit (e.g., overripe bananas or avocados)	Chocolate
Fava beans	Colas
Sausage, salami	Tea
Beef and chicken livers	Soy sauce
Monosodium glutamate	Beer, other wines
Sauerkraut	
Pickled fish	
Brewer's yeast	
Fermented products	
Sherry, liqueurs	
Red wine	

---

MAOI diets recommend restriction of cheese (except cream cheese and cottage cheese), red wine, sherry, liqueurs, pickled fish, overripe (aged) fruit, brewer's yeast, fava beans, beef and chicken liver, and fermented products. Some diets recommend restriction of all alcoholic beverages, coffee, chocolate, colas, tea, yogurt, soy sauce, avocados, and bananas. Notably, many of the restricted foods—for example, avocados and bananas—rarely cause hypertensive crisis. For example, an interaction may occur only if overripe fruit is eaten or, in the case of bananas, if the skin is eaten (which is an uncommon practice in the United States). Similarly, unless a person ingests large amounts of caffeine, the interaction is usually not clinically significant. Although there is greater risk of noncompliance with highly restrictive diets, the clinician, when discussing restrictions and cautions with the patient, should emphasize the need to adhere to dietary restrictions and the potential risks that arise by breaking the diet ([Gardner et al. 1996](#)).

In evaluating patients who may have had a drug-food reaction, the clinician should evaluate the hypertensive reaction and differentiate it from histamine headache, which also can occur with an MAOI. Histamine headaches are usually accompanied by hypotension, colic, loose stools, salivation, and lacrimation ([Cooper 1967](#)). The clinician should provide both oral and printed instructions about food and drug interactions to patients who are taking classic MAOIs.

## Drug-Drug Interactions

Drug-drug interactions are also extremely important concerns in patients taking irreversible MAOIs. The extensive inhibition of MAO enzymes by MAOIs raises the

potential for a number of interactions with other drugs (Table 8-4). Of particular importance, many over-the-counter medications can interact with MAOIs. These medications include cough syrups containing sympathomimetic agents, which in the presence of an MAOI can precipitate a hypertensive crisis.

**TABLE 8-4. Drug interactions with monoamine oxidase inhibitors (MAOIs)**

<b>Drug</b>	<b>Interaction</b>	<b>Comment</b>
Other MAOIs (e.g., furazolidone, pargyline, procarbazine)	Potential of side effects; convulsions possible	Allow at least 1 week before changing to another MAOI
Tricyclic antidepressants (TCAs) (e.g., maprotiline, bupropion)	Possibility of severe side effects, such as hypertension and convulsions; serotonin syndrome	Allow at least 2 weeks before changing to an MAOI; combinations have been used occasionally for refractory depression
Carbamazepine	Low possibility of interaction; similar to TCAs	Same as for TCAs

<b>Drug</b>	<b>Interaction</b>	<b>Comment</b>
Cyclobenzaprine	Low possibility of interaction; similar to TCAs	Same as for TCAs
Selective serotonin reuptake inhibitors (SSRIs)	Serotonin syndrome	Avoid combinations; allow at least 2 weeks before changing to an MAOI and 5 weeks if switching from fluoxetine to an MAOI
Stimulants (e.g., methylphenidate, dextroamphetamine)	Potential for increased blood pressure (hypertension)	Avoid combination
Buspirone	Potential for increased blood pressure (hypertension)	Avoid use; if used, monitor blood pressure

<b>Drug</b>	<b>Interaction</b>	<b>Comment</b>
Meperidine	Possibility of severe, potentially fatal interaction (see text); serotonin syndrome	Avoid combination
Dextromethorphan	Reports of brief psychosis	Avoid high doses
Direct sympathomimetics (e.g., L-dopa)	Increased blood pressure	Avoid use if possible; if they need to be used, use with caution
Indirect sympathomimetics	Hypertensive crisis possible	Avoid use
Oral hypoglycemics (e.g., insulin)	Worsening of hypoglycemia possible	Monitor blood sugar levels and adjust medications
Fenfluramine	Serotonin syndrome possible	Avoid use
L-Tryptophan	Serotonin syndrome possible	Avoid use

Another area of caution is the use of MAOIs in patients who need surgery. Potential interactions include those with narcotic drugs, especially meperidine. Meperidine

administered with MAOIs can produce a syndrome characterized by coma, hyperpyrexia, and hypertension. This syndrome has been reported primarily with phenelzine; however, it has also been reported with tranylcypromine ([Mendelson 1979](#); [Stack et al. 1988](#)). [Stack et al. \(1988\)](#) noted that this syndrome is most likely to occur with meperidine and that it may be related to that drug's serotonergic properties (similar to serotonin syndrome). Similar reactions have not been reported to any significant extent with other narcotic analgesics such as morphine and codeine. In fact, many patients probably receive these medications without problems. Only a small fraction of patients may have this interaction, and it could reflect a serotonin toxicity effect. In general, current opinion favors the use of morphine when intra- or postoperative narcotics are needed in patients taking MAOIs.

The issue of whether directly acting sympathomimetic amines interact with MAOIs is more controversial. Intravenous administration of sympathomimetic amines to patients receiving MAOIs does not provoke hypertension. When a bolus infusion of any of various catecholamines is given to healthy volunteer subjects who have been taking phenelzine or tranylcypromine for 1 week, a potentiation of the pressor effect of phenylephrine occurs, but no clinically significant potentiation of cardiovascular effects of NE, epinephrine, or isoproterenol occurs ([Wells 1989](#)).

In general, direct sympathomimetic amine-MAOI interactions do not appear to produce significant cardiovascular problems. However, there is a low incidence of hypertensive episodes in the presence of indirect sympathomimetics. Ideally, these compounds should not be used in patients who are receiving MAOIs. A direct-acting compound is preferable to an indirect-acting compound.

Caution should be exercised when using MAOIs in patients with pheochromocytoma or with cardiovascular, cerebrovascular, or hepatic disease. Because phenelzine tablets contain gluten, they should not be given to patients with celiac disease.

Each patient should be given a card indicating that he or she is taking an MAOI and instructed to carry the card at all times. A medical bracelet indicating that the wearer takes an MAOI is also a good idea.

## Specific Monoamine Oxidase Inhibitors

---

### Phenelzine

Phenelzine, a hydrazine derivative, is a potent irreversible MAOI and is the best studied of the MAOIs.

#### Pharmacokinetics

Phenelzine is a substrate as well as an inhibitor of MAO. Major identified metabolites of phenelzine include phenylacetic acid and *p*-hydroxyphenylacetic acid. Phenelzine undergoes acetylation, and therefore drug levels are lower in fast acetylators than in slow acetylators. However, because phenelzine is an irreversible inhibitor, plasma concentrations are not relevant. The antidepressant effect, the degree of inhibition of MAO, and the amount of free phenelzine excreted in the urine are all significantly greater in slow acetylators than in fast acetylators ([Baker et al. 1999](#)).

## **Indications**

Phenelzine is useful in the treatment of major depressive disorder, atypical depression, panic disorder, social phobia, and atypical facial pain (see section “Indications and Efficacy” earlier in this chapter).

## **Side Effects**

The primary side effects of phenelzine are similar to those of other MAOIs. Hepatitis secondary to phenelzine may occur in rare cases (<1 in 30,000). The most difficult side effect, often leading to discontinuation, is postural hypotension.

## **Contraindications**

The contraindications to phenelzine include known sensitivity to the drug, pheochromocytoma, congestive heart failure, and history of liver disease. (In addition, see sections “Dietary Interactions” and “Drug-Drug Interactions” earlier in this chapter.)

# **Isocarboxazid**

Isocarboxazid is an irreversible MAOI of the hydrazine type.

## **Pharmacokinetics**

Isocarboxazid is rapidly absorbed from the gastrointestinal tract and is metabolized in the liver. It is primarily excreted as hippuric acid. Its half-life is of little interest because it is an irreversible MAOI. Chemically, isocarboxazid is 5-methyl-3-isoxazolecarboxylic acid 2-benzylhydrazide. Isocarboxazid is a colorless crystalline substance with very little taste.

## **Indications**

Isocarboxazid is the least studied of the MAOIs. It is indicated for the treatment of depression.

### **Side Effects**

The side effects of isocarboxazid are similar to those of phenelzine, described earlier in this section. Postural hypotension is the most common problem.

### **Contraindications**

The contraindications to isocarboxazid are similar to those of phenelzine, described earlier in this section.

## **Tranylcypromine**

Tranylcypromine, a nonhydrazine irreversible MAOI, increases the concentration of NE, epinephrine, and 5-HT in the CNS. Tranylcypromine has a mild stimulant effect.

### **Pharmacokinetics**

Limited data exist on the pharmacokinetics of tranylcypromine. The drug is excreted within 24 hours. The dynamic effect lasts for up to 5 days after withdrawal. There is considerable debate about whether tranylcypromine is metabolized to amphetamine; most studies in the literature indicate that this does not occur.

### **Indications**

Tranylcypromine is indicated for the treatment of major depressive disorder without melancholia.

### **Side Effects**

The side effects of tranylcypromine are similar to those of other MAOIs. In addition, problems with physical dependence on tranylcypromine have been reported. Thus, withdrawal symptoms, such as anxiety, restlessness, depression, and headache, may occur. Syndrome of inappropriate antidiuretic hormone (SIADH) has been reported with tranylcypromine. Rare cases of toxic hepatitis have also been reported. Tranylcypromine can lead to increased agitation, insomnia, and restlessness, compared with phenelzine.

## Contraindications

The contraindications to tranylcypromine are the same as those for phenelzine, described earlier in this section. In addition, in view of the greater potential for hypertensive episodes, tranylcypromine should be used with particular caution in patients with cerebrovascular or cardiovascular disease.

## Moclobemide

Moclobemide, a reversible inhibitor of MAO-A enzyme ([Amrein et al. 1989](#)), has a higher potency in vivo than in vitro. Therefore, it has been suggested that moclobemide is a prodrug and that it is metabolized to a form with higher affinity for MAO-A than the parent compound. After single- or repeated-dose administration of moclobemide, the recovery of MAO-A activity is much quicker than that seen with other MAOIs. One of the metabolites of moclobemide does inhibit MAO-B; however, this action is minimally significant in humans. When administered to rats, moclobemide increases the concentration of 5-HT, NE, epinephrine, and DA in rat brain ([Haefely et al. 1992](#)). These effects are short lasting,

and they parallel the time course of MAO-A inhibition. In addition, unlike with irreversible inhibitors, repeated administration does not increase the inhibition.

Moclobemide only partially potentiates the blood pressor effect of oral tyramine ([DaPrada et al. 1989](#)). This is because it is a reversible inhibitor with a low affinity for the MAO isoenzymes and is easily displaced by the pressor amines ingested in food. On the basis of these studies, moclobemide is thought to be safer than irreversible MAOIs.

## Pharmacokinetics

After oral administration of moclobemide, peak plasma concentrations are reached within 1 hour. The drug is about 50% bound to plasma proteins and is extensively metabolized; only 1% of the compound is excreted (unchanged) in the urine. The half-life of the compound is approximately 12 hours. Moclobemide is extensively metabolized; 95% of the administered dose is excreted in the urine. The metabolites are pharmacologically inactive. The presence of food reduces the rate (but not the extent) of moclobemide absorption.

## Indications

Moclobemide has been studied in all types of depressive disorders ([Gabelic and Kuhn 1990](#); [Larsen et al. 1991](#); [Rossel and Moll 1990](#)). Controlled trials have found that it is superior to placebo. In addition, moclobemide has been found to be as effective as imipramine, desipramine, clomipramine, and amitriptyline in the treatment of depression. The dosage required is 300–600 mg/day.

Unlike the classic MAOIs, moclobemide has been found to be effective in treating both endogenous and nonendogenous depression. In addition, in combination with antipsychotics,

the drug seems to be effective in treating psychotic depression ([Amrein et al. 1989](#)). Moclobemide has also been effective in treating bipolar endogenous depression.

[Versiani et al. \(1992\)](#) compared phenelzine, moclobemide, and placebo and reported that both phenelzine and moclobemide were superior to placebo in treating patients with social phobia. Given the efficacy of classic MAOIs in the treatment of other psychiatric disorders, such as bulimia, panic disorder, and PTSD, it is likely that patients with such disorders would also respond to a reversible MAOI. Additional trials of moclobemide are required to confirm its utility in other psychiatric disorders.

## Side Effects

Nausea was the only side effect noted to be greater in patients taking moclobemide than in patients taking placebo. Thus, the profile of moclobemide seems to be ideal in that it causes few or no major side effects. Case reports have shown no toxicity after overdoses of up to 20 g ([Amrein et al. 1989](#)).

## Dietary Interactions

Intravenous tyramine pressor tests indicate that a single dose of moclobemide increases tyramine sensitivity ([Cusson et al. 1991](#)). However, this increase is marginal, compared with the increase associated with other MAOIs. Under most conditions, there appears to be limited drug-food interaction. However, to minimize even mild tyramine pressor effects, the recommended action is to administer moclobemide after a meal rather than before it. In a study in which tyramine was administered in doses up to 100 mg, inpatients pretreated with moclobemide had no significant changes in blood pressure. The drug also has minimal effect on cognitive performance and no effect on body weight or

hematological parameters ([Wesnes et al. 1989](#); [Youdim et al. 1987](#)).

## Drug-Drug Interactions

Several studies have examined potential drug-drug interactions with moclobemide ([Amrein et al. 1992](#)). No drug interaction with lithium has been reported. No interactions with benzodiazepines or antipsychotics have been reported ([Amrein et al. 1992](#)). Parallel data suggest that moclobemide can potentiate the effects of meperidine; therefore, the narcotic-MAOI interaction may occur. Combination with other antidepressants (including SSRIs) is best avoided in view of potential serotonin toxicity. Until proven otherwise, it would be prudent to avoid the combination of moclobemide with opiates like meperidine. A pharmacokinetic interaction has been observed with cimetidine that requires the reduction of the moclobemide dose because cimetidine reduces the clearance of moclobemide.

## Selegiline Hydrochloride

Selegiline hydrochloride is an irreversible MAO-B inhibitor ([Cesura and Pletscher 1992](#)). Its primary use is in the treatment of Parkinson's disease, as an adjunct to L-dopa and carbidopa. The average dosage for Parkinson's disease is 5–10 mg/day. The exact mechanism of action of MAO-B in Parkinson's disease is unknown ([Gerlach et al. 1996](#); [Hagan et al. 1997](#); [Lyytinen et al. 1997](#)).

## Pharmacokinetics

Selegiline is metabolized to levoamphetamine, methamphetamine, and *N*-desmethylselegiline. Selegiline hydrochloride undergoes significant first-pass metabolism

following oral administration. Transdermal delivery avoids the first-pass effect and provides greater levels of unchanged drug and reduced levels of metabolites compared with the oral regimen. The time to reach the peak is less than 1 hour. The elimination half-life of selegiline is about 1.5 hours. There is at least a threefold increase in the area under the curve (AUC) of selegiline with food ([Mahmood 1997](#)).

## **Indications and Efficacy**

The efficacy of selegiline in treating depression has not been well studied. [Quitkin et al. \(1984\)](#) showed that selegiline was superior to placebo administered to patients with depression in a 6-week double-blind study. Dosages of more than 10–20 mg/day were needed. The dosage required for treating depression may be much higher than that required to treat Parkinson's disease. At higher dosages, dietary interactions could occur. Early studies also found that selegiline is of modest benefit in patients with Alzheimer's disease ([Lawlor et al. 1997](#)).

## **Side Effects**

The few side effects that have been noted with selegiline include nausea, dizziness, and light-headedness. When the drug is abruptly discontinued, nausea, hallucinations, and confusion have been reported.

## **Dietary Interactions**

Because MAO-B is not involved in the intestinal tyramine interaction, dietary interaction with selegiline (at low dosages of 5–10 mg/day) would probably be minimal. An interaction between selegiline and narcotics has been reported and should be kept in mind.

## **Drug-Drug Interactions**

Selegiline's potential drug interactions are similar to those of other MAOIs, and there is a risk for serotonin syndrome if selegiline is combined with other drugs (including SSRIs) that can increase serotonin.

## **Selegiline Transdermal System**

The selegiline transdermal system (STS) was developed to overcome limitations of orally administered MAOIs, particularly dietary tyramine restrictions. STS does not overcome drug-drug interactions. It bypasses the gut, thereby reducing drug-food interactions. The pharmacokinetic and pharmacodynamic properties promote the inhibition of MAO-A and MAO-B in the CNS while avoiding significant inhibition of intestinal and liver MAO-A enzymes. Three different strengths of STS patch are currently marketed: 20 mg/20 cm<sup>2</sup>, 30 mg/30 cm<sup>2</sup>, and 40 mg/40 cm<sup>2</sup>. The three patch sizes deliver 24-hour doses of selegiline averaging 6 mg, 9 mg, and 12 mg, respectively. Use of the 6-mg patch does not call for dietary modification. A restricted "MAOI diet" is advised for the higher-dosage 9-mg and 12-mg patches to avoid any risk of hypertensive crisis. Patients are strongly advised to follow these restrictions.

## **Pharmacokinetics**

Following dermal application of the STS patch, 25%–30% of the selegiline content on average is delivered systemically over 24 hours. Consequently, the degree of drug absorption is one-third higher than the average amounts of 6–12 mg/24 hours. In comparison with oral dosing, transdermal dosing

results in substantially higher exposure to selegiline and lower exposure to metabolites.

## Indications and Efficacy

The efficacy of STS as a treatment for major depressive disorder was established in two placebo-controlled studies of 6 and 8 weeks' duration in adult outpatients with major depressive disorder. In both studies, patients were randomly assigned to double-blind treatment with drug patch or placebo. The 6-week trial showed that 6 mg/24 hours was significantly more effective than placebo, as assessed by scores on the 17-item Hamilton Rating Scale for Depression (Ham-D) ([Amsterdam 2003](#)). In an 8-week dosage titration trial, depressed patients receiving the drug patch (starting dosage was 6 mg/24 hours, with possible increases to 9 mg/24 hours or 12 mg/24 hours based on clinical response) showed significant improvement compared with those receiving placebo on the primary outcome measure, the 28-item Ham-D total score ([Feiger et al. 2006](#)). In another trial, 322 patients meeting DSM-IV-TR ([American Psychiatric Association 2000](#)) criteria for major depressive disorder who had responded during an initial 10-week open-label treatment phase were randomly assigned either to continuation at the same dose or to placebo under double-blind conditions for observation of relapse. In this double-blind phase, patients receiving continued STS experienced a significantly longer time to relapse ([Amsterdam and Bodkin 2006](#)). The efficacy was also studied in a double-blind study of depressed adolescents. There was no significant difference between patients receiving STS and those receiving placebo ([DelBello et al. 2014](#)).

## Side Effects

The main side effects with STS are diarrhea, skin irritation, and insomnia.

## **Drug-Drug Interactions**

Potential drug-drug interactions for STS are the same as for other MAOIs.

---

## **Conclusion**

---

Various MAOIs have been shown to be effective in treating a wide variety of psychiatric disorders, including depression, panic disorder, social phobia, and PTSD. The classic MAOIs are currently used only rarely as first-line medication because of potential dietary interactions and other long-term side effects. The reversible inhibitors of MAO-A enzyme, such as moclobemide, which have fewer side effects and no dietary restrictions compared with classic MAOIs, are unlikely to be introduced in the United States. In fact, the risk-benefit ratio for these compounds is highly favorable compared with other antidepressants. The MAO-B inhibitor selegiline is used to reduce the progression of Parkinson's disease. Its utility in treating other degenerative disorders is currently being assessed. STS reduces dietary interactions when used at low doses and is now approved for the treatment of major depressive disorder. New applications and a wider use of these compounds may be found in the near future.

## CHAPTER 9

# Tricyclic and Tetracyclic Drugs

J. Craig Nelson, M.D.

The tricyclic antidepressant agents hold an important place in the history of treatments for depression. They were the first class of antidepressant compounds to be widely used in depression and remained the first-line treatment for more than 30 years. The observation of their activity led to theories of drug action involving norepinephrine and serotonin. Indeed, this “psychopharmacological bridge” suggested that alterations of these neurotransmitters might cause depression ([Bunney and Davis 1965](#); [Prange 1964](#); [Schildkraut 1965](#)). The tricyclics were extensively studied, and through this study, the field developed several key principles to guide the management of depressive illness. For example, the importance not only of providing an adequate dosage and duration of medication during acute treatment but also of sustaining symptom improvements through the use of continuation treatment became recognized. The adverse events associated with the tricyclics required that psychiatrists become familiar with a variety of syndromes, such as anticholinergic delirium, delayed cardiac conduction, and orthostatic hypotension. The observation that tricyclic plasma concentrations varied widely stimulated interest in the relationship of these drug concentrations to hepatic metabolism and to clinical activity. The field was introduced to the concepts of genetic polymorphisms in the cytochrome P450 (CYP) enzyme system. Finally, our knowledge of how these drugs worked became the basis for the discovery of new drugs such as the selective serotonin reuptake inhibitors (SSRIs).

---

## History and Discovery

In 1957, Roland Kuhn, a Swiss psychiatrist, investigated the clinical effects of imipramine in human subjects in part to determine whether its sedative properties might be useful ([Kuhn 1958, 1970](#)). He found that although imipramine was not useful in calming agitated patients, the drug *did* appear to ameliorate symptoms in depressed patients.

After imipramine was introduced, several other antidepressant compounds were developed and marketed. These compounds had a basic tricyclic or tetracyclic structure and shared many of the secondary effects for which the tricyclics came to be known.

---

## Structure-Activity Relations

Tricyclic and tetracyclic compounds are categorized on the basis of their chemical structure ([Figure 9-1](#)). The tricyclics have a central three-ring structure, hence the name. The tertiary-amine tricyclics, such as amitriptyline and imipramine, have two methyl groups at the end of the side chain. These compounds can be demethylated to secondary amines, such as desipramine and nortriptyline. The tetracyclic compound maprotiline has a four-ring central structure. Five tertiary amines have been marketed in the United States—amitriptyline, clomipramine, doxepin, imipramine, and trimipramine. The three secondary-amine compounds are desipramine, nortriptyline, and protriptyline. All of these compounds, in addition to amoxapine and maprotiline, have been approved for use in major depressive disorder with the exception of clomipramine, which in the United States is approved for use only in obsessive-compulsive disorder (OCD).

**FIGURE 9-1.** Chemical structures of tricyclic and tetracyclic antidepressants.

The nature of the side chain appears to be important for the tricyclics' function. The tertiary tricyclic agents—amitriptyline, imipramine, and clomipramine—are more potent in blocking the serotonin transporter. The secondary tricyclics are much more potent in blocking the norepinephrine transporter (Table 9-1) (Bolden-Watson and Richelson 1993; Tatsumi et al. 1997).

The structure of amoxapine differs from the structures of the other tricyclics. With a central three-ring structure and a side chain unlike those of the tricyclics, amoxapine is structurally closer to the antipsychotic loxapine, from which it is derived. Similar to the secondary tricyclics, it is a potent norepinephrine reuptake inhibitor. Unlike all of the other compounds in this group, amoxapine, and particularly its metabolite 7-hydroxyamoxapine, blocks postsynaptic dopamine receptors (Coupet et al. 1979). As a result, it is the only compound in the group that has antipsychotic activity in addition to antidepressant effects.

Maprotiline also differs from the others in this group. Although maprotiline is tetracyclic, its side chain is identical to that in desipramine, nortriptyline, and protriptyline. As would be predicted from this similarity, maprotiline is most potent in blocking the norepinephrine transporter (Randrup and Braestrup 1977).

---

## Pharmacological Profile

---

### Reuptake Blockade

Early in the history of the tricyclic and tetracyclic antidepressants, the ability of these compounds to block the transporter site for norepinephrine was described ([Axelrod et al. 1961](#)) (see [Table 9-1](#)). The tertiary amines have greater affinity for the serotonin transporter, whereas the secondary amines are relatively more potent at the norepinephrine transporter. During the administration of amitriptyline, imipramine, or clomipramine, these tertiary amines are demethylated to secondary amines; thus, both serotonergic and noradrenergic effects occur. In addition, because dopamine is inactivated by norepinephrine transporters in the frontal cortex ([Bymaster et al. 2002](#)), norepinephrine reuptake inhibitors would be expected to increase dopamine concentrations in that region.

### Receptor Sensitivity Changes

The initial reuptake blockade described above is followed by a specific sequence of events ([Blier et al. 1987](#); [Charney et al. 1991](#); [Tremblay and Blier 2006](#)). Because the tertiary tricyclic compounds inhibit the uptake of serotonin, the levels of serotonin rise. As the result of inhibitory feedback from the presynaptic somatodendritic serotonin<sub>1A</sub> (5-HT<sub>1A</sub>) autoreceptor, the firing rate of the presynaptic serotonin neuron falls, and concentrations of 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of serotonin, decline rapidly. Over a 10- to 14-day period, the presynaptic autoreceptor is desensitized, and when this occurs, the tonic firing rate returns to its pretreatment rate. With both a normal firing rate and reuptake blockade, serotonin transmission is enhanced. The tricyclic agents also sensitize or upregulate postsynaptic 5-HT<sub>1A</sub> receptors ([de Montigny and Aghajanian 1978](#)). These changes further enhance the effects of serotonin.

The tricyclics also downregulate the 5-HT<sub>2</sub> receptors (; [Peroutka and Snyder 1980](#)). In preclinical experiments, when the 5-HT<sub>2</sub> receptor was blocked by an antagonist, the effects of serotonin were enhanced ([Lakoski and Aghajanian 1985](#); [Marek et al. 2003](#)). Some of the tricyclics—particularly amoxapine and doxepin, and to some extent amitriptyline—have 5-HT<sub>2</sub> antagonist properties relatively comparable to their reuptake potency (see [Table 9-1](#)) ([Tatsumi et al. 1997](#)).

The sequence of events with chronic dosing in the noradrenergic system is more complicated ([Tremblay and Blier 2006](#)). As in the serotonergic system, reuptake inhibition results in a rapid decline in norepinephrine turnover, as reflected by a drop in concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, and attenuation of the firing rate of the noradrenergic neuron. This effect appears to be mediated by the presynaptic somatodendritic  $\alpha_2$ -adrenergic autoreceptor, which provides inhibitory feedback to the presynaptic neuron. In contrast to the firing rate of serotonergic neurons, the firing rate of noradrenergic neurons remains inhibited with chronic treatment ([Szabo and Blier 2001](#)), suggesting that somatodendritic  $\alpha_2$  receptors do not desensitize. Norepinephrine concentrations do increase at postsynaptic sites such as the hippocampus and frontal cortex. This may indicate desensitization of terminal  $\alpha_2$  autoreceptors.

With chronic treatment, the postsynaptic  $\beta$ -adrenergic receptor is downregulated, or decreased in density (Sulser et al. 1978). Current evidence suggests that  $\beta$ -adrenergic receptor downregulation is likely a compensatory change. Overall, chronic administration of a norepinephrine reuptake inhibitor appears to override the downregulation of the postsynaptic  $\beta$ -receptor, resulting in enhanced noradrenergic transmission. This effect manifests as enhanced formation of the second messenger cyclic adenosine monophosphate (cAMP) (Duman et al. 1997) and is reflected clinically by a persistent increase in heart rate (Roose et al. 1998; Rosenstein and Nelson 1991).

## Secondary Effects

The tricyclic and tetracyclic compounds have a variety of additional actions mediated by other receptors (Cusack et al. 1994; Richelson and Nelson 1984) (see Table 9-1). For example, these compounds block muscarinic receptors, producing anticholinergic effects. Although these anticholinergic effects have generally been thought to mediate the adverse effects of tricyclics and tetracyclics, a double-blind randomized crossover study in 19 subjects with major depressive disorder found that the anticholinergic drug scopolamine had a beneficial effect on depressive and anxious symptoms (Furey and Drevets 2006). Consistent with this finding, donepezil, a cholinergic drug (a cholinesterase inhibitor), when given as an adjunct to an SSRI, increased the risk of depression relapse in older adults (Reynolds et al. 2011). The tricyclics also block histamine<sub>1</sub> (H<sub>1</sub>) receptors and  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptors, resulting in a variety of other effects (as discussed in the next section). Tricyclics act on voltage-gated sodium channels, which explains their adverse cardiac effects; however, these same actions may contribute to the beneficial effects of tricyclics on pain (Liang et al. 2014; Priest and Kaczorowski 2007). The potency of secondary effects of the tricyclics and tetracyclics varies considerably. Among the tricyclics, amitriptyline is the most anticholinergic and desipramine the least anticholinergic. Doxepin is the most potent H<sub>1</sub> antagonist among the tricyclics, but mirtazapine is even more potent. The consequences of these secondary effects are discussed below.

---

## Pharmacokinetics and Disposition

---

### Absorption

Absorption of the tricyclic and tetracyclic drugs occurs in the small intestine and is rapid and reasonably complete. Peak levels are reached within 2–8 hours following ingestion. Exceptions include protriptyline (peak levels reached between 6 and 12 hours after ingestion) and maprotiline (peak levels not reached until 8 hours or longer). Although peak levels may have implications for side effects, peak levels are relatively unimportant with respect to efficacy because the antidepressant action of these drugs occurs over several weeks.

### Volume of Distribution

The tricyclic and tetracyclic compounds are basic lipophilic amines and are concentrated in a variety of tissues throughout the body. As a result, they have a high volume of distribution. For example, concentrations of these drugs in cardiac tissue exceed concentrations in plasma.

## Plasma Protein Binding

The tricyclic and tetracyclic compounds are extensively bound to plasma proteins (e.g., 90% or greater) because of their lipid solubility. Exceptions are the hydroxy metabolites, which have lower plasma protein binding than the parent compounds.

## First-Pass Metabolism

Following absorption, the tricyclics are taken up in the circulation but pass first through the liver, and metabolism of the drug begins—the so-called first-pass effect. As a result, the amount of the compound that enters the systemic circulation is reduced.

## Hepatic Metabolism

Hepatic metabolism is the principal method of clearance for the tricyclic and tetracyclic compounds. Only a small portion of drug is eliminated by the kidneys. Rates of hepatic metabolism vary widely from person to person, resulting in dramatic differences in steady-state plasma concentrations. Elimination half-lives for most of the tricyclic and tetracyclic compounds average about 24 hours or longer; thus, the drugs can be given once a day (Table 9-2). Amoxapine has a shorter half-life than the other tricyclics and is an exception.

Hepatic metabolism of the tricyclics and tetracyclics occurs along two principal metabolic pathways. *Demethylation of the side chain* converts the tertiary amines to secondary amines. The other pathway in hepatic metabolism is *hydroxylation of the ring structure*, which produces hydroxy metabolites. In some cases, the levels of the metabolite are substantial. The concentration of 10-hydroxynortriptyline usually exceeds that of the parent compound (Bertilsson et al. 1979). Usually 2-hydroxydesipramine is present at levels approximately 40%–50% of those of the parent compound, but these ratios are quite variable and depend on the rate of hydroxylation (Bock et al. 1983; Potter et al. 1979). Hydroxyimipramine and hydroxyamitriptyline are present at very low concentrations and are clinically unimportant. The hydroxy metabolites are then conjugated and excreted. The conjugated metabolites are not active.

Hydroxynortriptyline and hydroxydesipramine both block the norepinephrine transporter (Bertilsson et al. 1979; Potter et al. 1979). Both have antidepressant activity (Nelson et al. 1988b; Nordin et al. 1987). The norepinephrine reuptake potency of hydroxydesipramine is comparable to that of the parent compound. There are two isomers of hydroxynortriptyline, *E*- and *Z*-10-hydroxynortriptyline. *E*-10-hydroxynortriptyline is present at levels four times higher than those of the *Z* isomer and is about 50% as potent as nortriptyline in blocking norepinephrine uptake.

The principal metabolic pathway for amoxapine is hydroxylation, during which 7-hydroxyamoxapine and 8-hydroxyamoxapine are produced (Coupet et al. 1979). These compounds differ: whereas 7-hydroxyamoxapine has high-potency antipsychotic properties but a short half-life, 8-hydroxyamoxapine is metabolized more slowly and appears to contribute to the drug's antidepressant action.

The CYP2D6 pathway appears to be responsible for hydroxylation of desipramine and nortriptyline (Brøsen et al. 1991). In fact, desipramine is considered to be the prototypic substrate for CYP2D6 because it has no other major metabolic pathways. Demethylation of the tertiary-amine compounds involves a number of CYP isoenzymes, including 1A2, 3A4, and 2C19. These hepatic isoenzymes are under the control of specific genes, and gene loci for several of these isoenzymes, including CYP2D6, have been identified. Approximately 5%–10% of Caucasians are homozygous for the recessive autosomal 2D6 trait, resulting in

deficient hydroxylation of desipramine and nortriptyline (Brøsen et al. 1985; Evans et al. 1980). These individuals are termed *poor metabolizers*, whereas those with adequate 2D6 enzyme are referred to as *extensive metabolizers*. Among individuals of Asian descent, approximately 50% carry the CYP2D6\*10 allele, which is associated with intermediate metabolism of 2D6 substrates (Ji et al. 2002). For example, the elimination half-life of nortriptyline is doubled in individuals homozygous for this allele (Yue et al. 1998). Approximately 20% of Asian individuals have a genetic polymorphism resulting in deficient CYP2C19 metabolism.

The variability in plasma concentrations that results from these metabolic differences is substantial. For example, in a sample of 83 Caucasian inpatients who were given a fixed dose (2.5 mg/kg) of desipramine, we observed steady-state plasma concentrations ranging from 20 ng/mL to 934 ng/mL (Nelson 1984).

## P-Glycoprotein and the Blood-Brain Barrier

P-glycoprotein (P-gp) is located at the blood-brain barrier and acts as an efflux pump. Its function is to protect the organism from exogenous compounds. It is hypothesized that by limiting uptake of antidepressants into the central nervous system (CNS), P-gp contributes to medication resistance. Most tricyclics are substrates of P-gp (Akamine et al. 2012; O'Brien et al. 2012). The effectiveness of P-gp is reduced in the presence of P-gp inhibitors (e.g., verapamil and quinidine), and these agents would be expected to raise CNS concentrations of P-gp substrates (Weiss et al. 2003); however, the utility of adjunctive treatment with a P-gp inhibitor to improve outcomes has not been demonstrated.

P-gp is encoded by the *ABCB1* gene. Polymorphisms of the *ABCB1* gene decrease the efficiency of P-gp and should result in higher CNS concentrations of P-gp substrates. The first study to examine the contribution of the *ABCB1* gene to antidepressant effectiveness found that remission of depression was more likely if *ABCB1* polymorphisms were present and the antidepressant was a P-gp substrate, but found no association if the antidepressant was not a P-gp substrate (Uhr et al. 2008). Yet a recent review and meta-analysis of the association of *ABCB1* variants and outcome reported considerable variability in the findings of 16 studies conducted, both in terms of whether any association was found and in terms of which genetic variant was associated with greater response (Breitenstein et al. 2015). Furthermore, the two largest studies included in this meta-analysis (GENDEP [Genome-Based Therapeutic Drugs for Depression] and STAR\*D [Sequenced Treatment Alternatives to Relieve Depression]) found that none of the *ABCB1* variants was associated with response to P-gp substrate antidepressants. The lack of association in the largest studies suggests limited applicability of the *ABCB1* genotype as a predictor of response in depression.

## Steady-State Concentrations

*Steady state* is the point on a fixed dose at which plasma concentrations of the drug reach a plateau. Steady state is achieved after five half-lives. If blood level monitoring is employed, a sample is drawn immediately before the next dose is scheduled to be given, usually in the morning, after the patient's level has reached steady state. Steady-state drug concentrations should remain relatively stable as long as the dosage is constant, the patient is adherent to the medication regimen, and no interactive drugs are added. If only one sample is drawn, the clinician should bear in mind that even if the laboratory error is

low, there will be moderate biological variability ( $\pm 10\%$ – $15\%$ ). Single blood level samples are better viewed as estimates than as precise measures.

When the drug concentration is measured, the total of both the free and bound drug is reported. Drug concentrations in the cerebrospinal fluid are proportional to the free levels. The *free concentration* is dependent on dose and hepatic clearance but is not affected by plasma protein binding ([Greenblatt et al. 1998](#)). Factors that affect plasma proteins—malnutrition, inflammation—may lead to changes in the bound fraction, but the absolute free concentration is unaffected.

## Linear Kinetics

Most of the tricyclics have linear kinetics; that is, concentration increases in proportion to dose within the therapeutic range. There are exceptions. Desipramine, for example, has nonlinear kinetics at the usual dosage range ([Nelson and Jatlow 1987](#)). In cases of overdose, nonlinear changes are more likely to occur, and the clinician cannot assume that usual rates of drug elimination will be maintained.

## Effects of Aging

Changes in the pharmacodynamics and pharmacokinetics of medications occur with aging, yet some are relatively unimportant ([Greenblatt et al. 1998](#)). The ratio of fat to lean body mass increases, and cardiac output and hepatic blood flow decrease. There may be further changes associated with medical illness. But the clinical importance of these changes is usually relatively minor because of the dramatic variability of hepatic metabolism. The activity of the CYP3A4 pathway does slow with age ([von Moltke et al. 1995](#)), and concentrations of the tertiary amines are increased somewhat in older individuals ([Abernethy et al. 1985](#)). Alternatively, most studies of nortriptyline ([Katz et al. 1989](#); [Young et al. 1984](#)) and desipramine ([Abernethy et al. 1985](#); [Nelson et al. 1985, 1995](#)) indicate that ratios of blood level to dosage of these drugs are relatively unaffected by aging, suggesting that the 2D6 isoenzyme is not similarly affected. Renal clearance of the hydroxy metabolites does decrease with age ([Nelson et al. 1988a](#); [Young et al. 1984](#)). As a result, concentrations of hydroxynortriptyline may be substantially elevated in older patients.

In children, the clearance of tricyclic compounds is increased. Half-lives of imipramine are shorter, and ratios of desmethyylimipramine to imipramine are higher, consistent with more rapid metabolism ([Geller 1991](#); [Rapoport and Potter 1981](#)). Alternatively, a study of desipramine in children found that the clearance of both desipramine and hydroxydesipramine was increased, so that hydroxy metabolite–parent compound ratios were not elevated ([Wilens et al. 1992](#)).

## Relationship of Plasma Concentration to Clinical Action

### Plasma Concentration and Response

Marked interindividual variability of tricyclic plasma concentrations was described by [Hammer and Sjöqvist in 1967](#). This finding suggested that drug level monitoring might ensure that therapeutic blood levels are achieved and might help to avoid toxic levels. In carefully selected inpatients with endogenous or melancholic major depression, treatment

with adequate levels of imipramine or desipramine resulted in robust response rates of about 85% (Glassman et al. 1977; Nelson et al. 1982). But similar relationships have proven difficult to demonstrate in depressed outpatients. In outpatients, drug-placebo differences are often small, and the effect of drug treatment is harder to detect. Depressed outpatients may be more heterogeneous and include individuals who are not responsive to any drug treatment. It is logical to conclude that blood level relationships determined in severely depressed inpatients might be used as a guide for treatment of outpatients, but this assumption has not been empirically validated.

A task force of the American Psychiatric Association (1985) that reviewed studies relating tricyclic plasma levels and response concluded that a relationship had been demonstrated for imipramine, desipramine, and nortriptyline (see Table 9-2). Data on the relationship between blood level and response in depression are limited or conflicting for the other tricyclic and tetracyclic compounds.

### Plasma Concentration and Toxicity

Blood level monitoring may help to avoid toxicity. The risk of delirium is substantially increased at amitriptyline plasma concentrations above 450 ng/mL and is moderately increased at concentrations above 300 ng/mL (Livingston et al. 1983; Preskorn and Simpson 1982). But amitriptyline is the most anticholinergic tricyclic and is most likely to produce delirium. The risk of first-degree atrioventricular block is also increased at imipramine plasma concentrations greater than 350 ng/mL (Preskorn and Irwin 1982). The risk of seizures also increases at higher dosages and, presumably, higher blood levels, although a clear plasma level threshold for seizures has not been demonstrated. Following overdose, tricyclic blood levels greater than 1,000 ng/mL can be achieved, and the risks of delirium, stupor, cardiac abnormalities, and seizures are all substantially increased (Preskorn and Irwin 1982; Rudorfer and Young 1980; Spiker et al. 1975). The value of blood level monitoring for avoidance of serious adverse effects has been difficult to demonstrate; given that rates of serious toxicity are low, large samples would be required to demonstrate any increase in risk at higher blood levels.

If blood level monitoring is undertaken, the clinician should bear in mind that many factors—including laboratory variability, blood sampling errors, missed doses, and biological variability—can affect drug concentrations. For this reason, the clinician should not view the concentration reported as a precise measure. Yet because concentrations vary across such a wide range, it may be very helpful to know whether the level is low (e.g., 25–75 ng/mL), moderate (e.g., 100–300 ng/mL), or high (e.g., 300–1,000 ng/mL).

### Prospective Dosing Techniques

The demonstrated relationship between timed drug concentrations after a single tricyclic dose and the steady-state level achieved suggests the possibility of using plasma levels obtained early in treatment to rapidly adjust the dose. A clinical study using desipramine found that treatment could be initiated at full dosage once the dosage needed to reach a therapeutic level was determined from a 24-hour blood level following a test dose (Nelson et al. 1987). However, the practical application of this method was limited. Most laboratories are not prepared to determine drug concentrations accurately at very low levels (as needed following a test dose) and are unable to report results quickly. A more practical and clinically feasible method is to start the drug at a low or moderate fixed dose, obtain a blood sample after 5–7 days on that dose, and then make further adjustments based on that level. There are exceptions. Elderly depressed patients often require

gradual dosing in order to assess tolerance. In patients with panic attacks, lower starting doses are employed to avoid exacerbation of panic attacks.

---

## Mechanism of Action

---

Early studies observed that the tricyclic agents blocked uptake of monoamines at the norepinephrine and serotonin transporters ([Axelrod et al. 1961](#)). This drug effect was quickly put forward as a possible mechanism of action. The observation that reserpine, which depletes presynaptic catecholamines, might induce depression in vulnerable individuals supported this hypothesis ([F.K. Goodwin and Bunney 1971](#)). Confirmation that norepinephrine and serotonin do in fact mediate the action of monoamine reuptake inhibitors was provided by subsequent challenge studies in depressed patients. For example, administration of a tryptophan-free diet rapidly depletes serotonin and causes relapse in depressed patients who have been successfully treated with a serotonin reuptake inhibitor but not a norepinephrine reuptake inhibitor ([Delgado et al. 1990](#)). Alternatively, administration of  $\alpha$ -methyl-*p*-tyrosine (AMPT), which interrupts the synthesis of catecholamines, caused relapse in patients who were being successfully treated with noradrenergic agents but not those receiving serotonergic drugs ([Delgado et al. 1993](#)). These studies provide supporting evidence that serotonin and norepinephrine mediate antidepressant effects, but they do not necessarily imply that alterations in these neurotransmitter systems are central to the etiology of depression.

Subsequent research on the mechanism of action of the tricyclics and other antidepressant drugs has shifted to include consideration of factors affecting postsynaptic signal transduction ([Manji et al. 1995](#)). Such factors include coupling of G proteins to the adrenergic receptor or to adenylyl cyclase and the activity of membrane phospholipases and protein kinases. Other newer targets, including glucocorticoid receptors ([Barden 1996](#)), neurotrophic factors ([Duman et al. 1997](#)), and gene expression ([Lesch and Manji 1992](#); [Nibuya et al. 1996](#); [Schwaninger et al. 1995](#)), have been explored.

## Indications and Efficacy

---

### Major Depressive Disorder

The efficacy of the tricyclic and tetracyclic compounds in major depression is well established. The evidence for their effectiveness has been reviewed previously ([Agency for Health Care Policy and Research 1993](#); [Davis and Glassman 1989](#)). Imipramine is the most extensively studied tricyclic antidepressant, in part because new drugs were often compared with it. In 30 of 44 placebo-controlled studies, imipramine was more effective than placebo. If data from these studies are combined, 65% of 1,334 patients *completing* treatment with imipramine were substantially improved, whereas 30% of those on placebo improved. *Intention-to-treat* response rates for placebo-controlled studies of imipramine in outpatients were 51% for imipramine and 30% for placebo ([Agency for Health Care Policy and Research 1993](#)). The other tricyclic and tetracyclic antidepressants appeared comparable to imipramine in efficacy.

The tricyclic compounds are also effective when used for maintenance treatment. [Frank et al. \(1990\)](#) found that imipramine, at full dosage, effectively maintained nearly 80% of

the depressed patients for a 3-year period, compared with 10% of those on placebo. In this study, maintenance psychotherapy had an intermediate effect, with about 30% of the patients remaining well. In practice, clinicians may encounter patients with chronic depression, with residual symptoms, or with comorbid medical and psychiatric disorders. For such patients, the effects of maintenance treatment are less robust.

The U.S. Food and Drug Administration (FDA) has approved all of the tricyclic and tetracyclic compounds discussed in this chapter for the treatment of depression, with the exception of clomipramine. In Europe, clomipramine is also used for depression; in fact, it is regarded by many as the most potent antidepressant.

## Depression With Melancholic Features (Severe Depression)

The efficacy of the tricyclic compounds appears to vary in different subtypes of depression. The early studies of tricyclic compounds were frequently conducted in hospitalized patients with severe or melancholic depression, and in these patients the tricyclics were found to be effective. In fact, the tricyclics may be especially effective in this group. Two studies of imipramine and desipramine found rates of response of about 85% in severely depressed hospitalized patients who did not have a history of treatment-resistant depression, did not have prominent personality disorder, received an adequate plasma concentration of the drug, and completed treatment ([Glassman et al. 1977](#); [Nelson et al. 1982](#)).

When the SSRIs were introduced, it was suggested that they might be less effective than the tricyclic antidepressants in treating severe or melancholic depression. However, in a large meta-analysis of more than 100 comparison studies, [Anderson \(2000\)](#) found that tricyclic antidepressants and SSRIs had comparable efficacy. In a separate meta-analysis of 25 inpatient studies ([Anderson 1998](#)), the advantage of the tricyclics appeared limited to those with dual action, namely amitriptyline and clomipramine. In outpatient populations, the designation of melancholia does not appear to predict an advantage for tricyclic antidepressants versus SSRIs ([Anderson and Tomenson 1994](#); [Montgomery 1989](#)).

## Depression With Anxious Distress

The use of tricyclics in anxious depression—or *depression with anxious distress* in DSM-5 ([American Psychiatric Association 2013](#)) terminology—has been frequently studied. Doxepin, amoxapine, and maprotiline have received FDA approval for use in patients with depression and symptoms of anxiety. Direct comparison studies, however, have found little indication that one tricyclic is better than another for treatment of anxious depression. Compared with depressed patients who are not prominently anxious, depressed patients who are anxious may respond less well to amitriptyline ([Kupfer and Spiker 1981](#)), imipramine ([Roose et al. 1986](#)), and desipramine ([Nelson et al. 1994](#)). Yet these drugs are still more effective than placebo in anxious depressed patients, and it is not established that another drug class is more effective in these patients.

## Depression With Atypical Features

A series of studies examined the efficacy of imipramine in depressed patients with atypical features ([Liebowitz et al. 1984, 1988](#)). Imipramine was more effective than placebo but significantly less effective than the monoamine oxidase inhibitor (MAOI) phenelzine. Other investigators have reported the value of switching from a tricyclic to an MAOI in tricyclic-refractory depressed patients with atypical features ([McGrath et al. 1987](#); [Thase et al. 1992](#)). In fact, the validity and utility of atypical depression were in large part supported by this observed differential response.

## Depression With Psychotic Features

In 1975, [Glassman et al.](#) observed that imipramine was less effective in patients with major depression who had delusions. Subsequently, [Chan et al. \(1987\)](#) reviewed several studies involving more than 1,000 patients and found that antidepressants—usually tricyclics—given alone were effective in approximately two-thirds of depressed patients without psychosis but in only about one-third of those with psychotic features. Several open studies reviewed elsewhere ([Nelson 1987](#)) and one prospective study ([Spiker et al. 1985](#)) found that the tricyclics, when combined with an antipsychotic, are effective in psychotic depression.

[Anton and Burch \(1990\)](#) suggested that because of its antipsychotic effects, amoxapine might be effective for psychotic depression. In a double-blind study, these researchers demonstrated that amoxapine was comparable in efficacy to the combination of perphenazine and amitriptyline in treating psychotic depression ([Anton and Burch 1990](#)).

## Bipolar Depression

Forty years ago, it was suggested that the MAOI antidepressants might be more effective than the tricyclics in treating bipolar depression ([Himmelhoch et al. 1972](#)). Later, [Himmelhoch et al. \(1991\)](#) demonstrated in a double-blind study that tranylcypromine was more effective than imipramine for bipolar depression. Because tricyclics are more likely than other agents to induce mania ([Wehr and Goodwin 1987](#)), they are not recommended for monotherapy of bipolar depression.

## Persistent Depressive Disorder (Dysthymia)

The new DSM-5 diagnostic category *persistent depressive disorder (dysthymia)* includes both chronic major depressive disorder and dysthymia. Imipramine appears to be effective in treating chronic depression and to be relatively comparable to sertraline in efficacy ([Keller et al. 1998](#); [Kocsis et al. 1988](#)). Imipramine and desipramine have both been studied in controlled trials in dysthymia. Imipramine was found to be more effective than placebo for acute treatment ([Thase et al. 1996](#)), and desipramine was more effective than placebo for maintenance treatment ([Miller et al. 2001](#)) of dysthymia.

## Late-Life Depression

[Gerson et al. \(1988\)](#) reviewed studies of tricyclic antidepressants in older patients reported prior to 1986. They found 13 placebo-controlled trials but noted several methodological problems. Although tricyclics were effective, overall response rates in older patients appeared to be lower than rates in nonelderly patients ([Agency for Health](#)

Care Policy and Research 1993). Katz et al. (1990) performed one of the first placebo-controlled trials of nortriptyline in the treatment of patients older than 80 years living in a residential care facility. Nortriptyline was more effective than placebo. The doses employed and levels achieved were similar to those in younger subjects. This study remains the only study to date showing an advantage for an antidepressant over placebo in depressed nursing home patients.

## Depression in Children

In children and adolescents, the tricyclic antidepressants have not demonstrated superiority over placebo (Ryan 1992).

## Panic Disorder

Although none of the tricyclic or tetracyclic drugs is approved for use in panic disorder, imipramine was the first drug described for use in this disorder (Klein 1964). The efficacy of both tertiary and secondary tricyclics has been demonstrated in controlled trials (Jobson et al. 1978; Munjack et al. 1988; Zitrin et al. 1980). In treating this disorder, the drug is initiated at a low dose to avoid exacerbation of panic symptoms.

## Obsessive-Compulsive Disorder

Unlike depression, which responds to a variety of antidepressant agents, OCD appears to require treatment with a serotonergic agent. Clomipramine, the most serotonergic of the tricyclics, is approved by the FDA for use in OCD, and its efficacy in this disorder is well established (Greist et al. 1995). Studies comparing its effectiveness with that of noradrenergic agents such as desipramine found that clomipramine was substantially superior (Leonard et al. 1989). Although the SSRIs are effective in treating OCD, there is a suggestion that clomipramine may be superior (Greist et al. 1995). Whether this suggested superiority is due to the dual mechanism of clomipramine or to other factors is unclear.

## Attention-Deficit/Hyperactivity Disorder

The efficacy of the stimulant drugs in treating attention-deficit/hyperactivity disorder (ADHD) is well established. The tricyclics, especially desipramine, also appear to be of value. In one study, desipramine, given at dosages greater than 4 mg/kg for 3–4 weeks, was effective in two-thirds of the children, whereas placebo was effective in only 10% (Biederman et al. 1989). Desipramine was also found to be more effective than placebo in adults with ADHD (Wilens et al. 1996). One of the advantages of desipramine is its low potential for abuse. Unfortunately, five cases of sudden death were reported in the early 1990s in children being treated with desipramine (Riddle et al. 1991, 1993). All were under the age of 12 years. As a result, desipramine is contraindicated in children younger than 12 years (discussed in greater detail below; see section “Side Effects and Toxicology”). Given that tricyclics as a group share the same adverse cardiac effects, there is reason to be concerned that other tricyclics might also have safety issues in young children (see also Chapter 55, “Treatment of Child and Adolescent Disorders”).

## Pain Syndromes

The tricyclics and the tetracyclic maprotiline have been widely used in various chronic pain syndromes. In a review of the literature, [O'Malley et al. \(1999\)](#) identified 56 controlled studies involving tricyclic antidepressant therapy for various pain syndromes, including headache (21 studies), fibromyalgia (18 studies), functional gastrointestinal syndromes (11 studies), idiopathic pain (8 studies), and tinnitus (2 studies); and [Salerno et al. \(2002\)](#) identified 7 more placebo-controlled trials of tricyclics or maprotiline used for chronic back pain. These agents were quite effective; the mean effect size (0.87) and the drug-placebo difference in response rates (32%) in the pain trials were more robust than those usually observed in placebo-controlled studies in depression. The analgesic effects of these compounds were not simply the result of their antidepressant effects.

The mechanism of these agents' analgesic effects appears to differ from that of their antidepressant effects. The antinociceptive actions of the antidepressants result from actions on descending norepinephrine and serotonin pathways in the spinal cord ([Yoshimura and Furue 2006](#)). In animals, the antinociceptive effects of norepinephrine reuptake inhibitors and combined norepinephrine-serotonin reuptake inhibitors appear to be more potent than those of SSRIs ([Mochizuki 2004](#)). In humans, there is some evidence that the combined-action agents amitriptyline and clomipramine are more effective than the SSRI fluoxetine ([Max et al. 1992](#)) or the norepinephrine-selective agents maprotiline ([Eberhard et al. 1988](#)) and nortriptyline ([Panerai et al. 1990](#)). In humans, antidepressant dosing and timing of effects for pain differ from those for depression. For example, usual dosages of amitriptyline required for pain management ( $\leq 75$  mg/day) are lower than those required to treat depression (15–300 mg/day), and response occurs more quickly, usually within the first 1 or 2 weeks.

## Other Indications

Imipramine has been used for treatment of nocturnal enuresis in children, with FDA approval, and controlled trials indicate efficacy ([Rapoport et al. 1980](#)). The dose of imipramine is usually 25–50 mg at bedtime. Amitriptyline and nortriptyline also appear to be useful for this indication, although they are not FDA approved for use in the disorder. The mechanism of action is unclear but may in part be anticholinergic. Given the serious cardiac risks attached to desipramine's use in children younger than 12 years (discussed in earlier subsection "Attention-Deficit/Hyperactivity Disorder"), concerns have been raised regarding whether tricyclics other than desipramine might also pose safety risks in this population. However, the low doses used in imipramine treatment of pediatric nocturnal enuresis may reduce this risk.

Tricyclic antidepressant drugs have been extensively studied in patients with schizophrenia. However, in the absence of a major depressive episode, these agents appear to be of limited value ([Siris et al. 1978](#)).

The more sedating tricyclics have been used to treat insomnia, and doxepin (as Silenor) is FDA approved for this indication. Because of its antihistaminic effects, doxepin has also been used for pruritis and is FDA indicated (as Zonalon) for short-term management of moderate pruritis in atopic dermatitis and lichen simplex chronicus.

## Side Effects and Toxicology

---

Distinguishing side effects during tricyclic treatment from the somatic symptoms of depression can be complicated. During treatment, patients may attribute somatic symptoms to drug side effects even if the symptoms were preexisting. One study found that the strongest predictor of overall somatic symptom severity was the severity of the depression at the time of assessment (Nelson et al. 1984).

Another general factor contributing to side effects is the patient's vulnerability. For example, one of the best predictors of orthostatic hypotension during treatment is the presence of orthostatic hypotension prior to treatment (Glassman et al. 1979). Seizures are most likely in a patient with a history of seizures (Rosenstein et al. 1993). Cardiac conduction problems are most likely to occur in patients with preexisting conduction delay (Roose et al. 1987a).

Antidepressant drugs do have effects on a variety of organs and can produce adverse effects. The in vitro potency or affinity of antidepressant compounds for various receptor sites (see Table 9-1) is one factor determining the likelihood that specific side effects will be produced. A related issue is how the in vitro potency of a secondary effect relates to the potency of the primary action of the drug. If the secondary effect is more potent, it will occur at concentrations below the therapeutic level of the drug. For example, orthostatic hypotension often occurs at plasma concentrations below the usual therapeutic threshold. Alternatively, the proarrhythmic and proconvulsant effects of the tricyclic antidepressants become more pronounced at elevated blood levels or those encountered in overdose.

## Central Nervous System Effects

The principal action of the tricyclic and tetracyclic agents in the CNS is to reduce the symptoms of depression. Nondepressed subjects given imipramine may feel sleepy, quieter, light-headed, clumsy, and tired. These effects are generally unpleasant (DiMascio et al. 1964).

The anticholinergic and antihistaminic effects of the tricyclics and tetracyclics can produce confusion or delirium. The incidence of delirium is dose dependent, with delirium risk increasing at blood levels above 300 ng/mL (Livingston et al. 1983; Preskorn and Simpson 1982). The risk of delirium appears to be higher with the more anticholinergic agents, such as amitriptyline. Patients with concurrent dementia are particularly vulnerable to the development of delirium, and the more anticholinergic tricyclics should be avoided in such patients. Intramuscular or intravenous physostigmine can be used to reverse or reduce the symptoms of delirium, but physostigmine's short duration of action makes its continued use difficult.

Seizures can occur with all of the tricyclic and tetracyclic agents and are dosage and blood level related (Rosenstein et al. 1993). For clomipramine, the risk of seizures is reported to be 0.5% at dosages up to 250 mg/day. At clomipramine dosages above 250 mg/day, the seizure risk increases to 1.67% (clomipramine new drug application data on file with the FDA). The seizure risk for such as imipramine and amitriptyline were not well established at the time of marketing. Two of the largest studies found that seizure risk varied from 0 to 0.6% or 0.7% for various tricyclic compounds and were clearly dose related (Jick et al. 1983; Peck et al. 1983). The risk of seizures is substantially increased following overdose (Spiker et al. 1975). The cumulative data to date suggest that amoxapine, clomipramine, and maprotiline present the highest seizure risk among this group of agents (Johannessen Landmark et al. 2016). The risk of convulsions is increased in patients with predisposing factors such as a history of seizures, the presence of brain

injury, or the use of antipsychotics. The mechanism by which tricyclics produce seizures is not well understood.

A fine, rapid tremor can occur with use of tricyclic agents. Because tremors are dose dependent, tend to occur at higher blood levels, and are not typical depressive symptoms, development of a tremor may be a clinical indicator of an elevated blood level ([Nelson et al. 1984](#)).

Because the 7-hydroxy metabolite of amoxapine has antipsychotic properties, administration of amoxapine carries the potential risk of neuroleptic malignant syndrome and tardive dyskinesia. Although these adverse events are rare, the seriousness of the risk and the availability of alternatives suggest that use of amoxapine should be reserved for patients whose clinical condition warrants treatment with an agent possessing antipsychotic properties.

## Anticholinergic Effects

The tricyclics block muscarinic receptors and can cause a variety of anticholinergic side effects, such as dry mouth, constipation, blurred vision, and urinary hesitancy. These effects can precipitate an ocular crisis in patients with narrow-angle glaucoma. The tricyclic and tetracyclic compounds vary substantially in their muscarinic potency (see [Table 9-1](#)). Amitriptyline is the most potent, and desipramine is the least anticholinergic. Amoxapine and maprotiline also have minimal anticholinergic effects. Anticholinergic effects can contribute to tachycardia, but tachycardia also occurs as a result of stimulation of  $\beta$ -adrenergic receptors in the heart. Thus, tachycardia also occurs in patients receiving desipramine, which is minimally anticholinergic ([Rosenstein and Nelson 1991](#)).

Although anticholinergic effects are annoying, they are usually not serious. They can, however, become severe. An ocular crisis in patients with narrow-angle glaucoma is an acute condition associated with severe pain. Urinary retention can be associated with stretch injuries to the bladder. Constipation can progress to severe obstipation. (Paralytic ileus has been described but is rare.) In these conditions, medication must be discontinued and appropriate supportive measures instituted. Elderly patients are at greatest risk for severe adverse consequences. The incidence of severe anticholinergic adverse reactions is increased by concomitant administration of other anticholinergic agents. Use of a tricyclic with weak anticholinergic properties, such as nortriptyline or desipramine, can help to reduce the likelihood of these problems.

Anticholinergic side effects may benefit from other interventions. Bethanechol (Urecholine) at a dosage of 25 mg three or four times a day may be helpful in patients with urinary hesitancy. The regular use of stool softeners helps to manage constipation. Patients with narrow-angle glaucoma who are receiving pilocarpine eye drops regularly can be treated with a tricyclic, as can those who have had an iridectomy. Tricyclic agents do not affect patients with chronic open-angle glaucoma.

## Antihistaminic Effects

Several of the tricyclic compounds and maprotiline have clinically significant antihistaminic effects. Doxepin, the most potent  $H_1$  receptor antagonist among the tricyclics, is more potent than diphenhydramine but less potent than mirtazapine. Central  $H_1$  receptor blockade can contribute to sedation and delirium and also appears to be related to the increased appetite and associated weight gain that patients may develop

with chronic treatment. Because of their sedating effects, the tricyclic antidepressants, especially amitriptyline, have been used as hypnotics. Given their cardiac effects and lethality in overdose, this practice should be discouraged.

## Cardiovascular Effects

Orthostatic hypotension is one of the most common reasons for discontinuation of tricyclic antidepressant treatment (Glassman et al. 1979). It can occur with all of the tricyclics but appears to be less pronounced with nortriptyline (Roose et al. 1981; Thayssen et al. 1981). The  $\alpha_1$ -adrenergic blockade associated with the tricyclics contributes to orthostatic hypotension; however, it is the postural reflex that is primarily affected. Resting supine blood pressure may be unaffected or can even be elevated (Walsh et al. 1992). Orthostatic hypotension is most likely to occur or is most severe in patients who have preexisting orthostatic hypotension (Glassman et al. 1979). It is also aggravated by concurrent antihypertensive medications, especially volume-depleting diuretic agents. The elderly are more likely to have preexisting hypotension and are also more vulnerable to the consequences of orthostatic hypotension, such as falls and hip fractures.

Orthostatic hypotension often occurs at low medication blood levels. Gradual dosage adjustment may allow accommodation to the subjective experience of light-headedness, but the actual orthostatic blood pressure changes do not accommodate within a reasonable period of time (e.g., 4 weeks) (Roose et al. 1998). As a consequence, patients who experience serious symptomatic orthostatic hypotension may not be treatable with a tricyclic antidepressant. Fludrocortisone (Florinef) has been used to raise blood pressure, but in this author's experience it is not very effective. If patients are receiving antihypertensives, it may be possible and helpful to reduce the dosage of these agents.

Desipramine has been reported to raise supine blood pressure in young women (ages 18–45 years), although it is not clear that this effect is limited to that age group (Walsh et al. 1992). The elevation in blood pressure may be similar to that reported for venlafaxine.

Tachycardia occurs with all of the tricyclics, not just the more anticholinergic agents. Both supine and postural pulse changes can occur, and the standing pulse can be markedly elevated. A study of nortriptyline, dosed to a therapeutic plasma concentration, found a mean pulse increase of 11% (8 beats per minute) (Roose et al. 1998). Patients do not accommodate to the pulse rise, which can persist for months. Tachycardia is more prominent in young patients, who appear to be more sensitive to sympathomimetic effects, and is one of the most common reasons for drug discontinuation in adolescents. A persistent pulse rise, however, increases cardiac work and may be clinically significant in patients with ischemic heart disease.

The effect of tricyclic antidepressants on cardiac conduction has been a subject of great interest. Cardiac arrhythmia is the principal cause of death following tricyclic overdose (Spiker et al. 1975). Apparently, through inhibition of sodium/potassium ( $\text{Na}^+/\text{K}^+$ ) adenosine triphosphatase (ATPase), the tricyclics stabilize electrically excitable membranes and delay conduction, particularly His ventricular conduction. Consequently, the tricyclics have type I antiarrhythmic qualities or quinidine-like effects.

At therapeutic blood levels, the tricyclics can have beneficial effects on ventricular excitability. In patients with preexisting conduction delay, however, the tricyclic antidepressants can cause heart block (Glassman and Bigger 1981; Roose et al. 1987b). A pretreatment QTc interval of 450 milliseconds or greater indicates that conduction is already delayed and that the patient is not a candidate for tricyclic antidepressant treatment. High drug plasma levels (e.g., imipramine plasma concentrations  $>350$  ng/mL)

increase the risk of first-degree atrioventricular heart block ([Preskorn and Irwin 1982](#)). The tricyclic antidepressants do not reduce cardiac contractility or cardiac output ([Roose et al. 1987a](#)).

[Glassman et al. \(1993\)](#), noting that the type I antiarrhythmic drugs routinely given following myocardial infarction actually increase the risk of sudden death, suggested that the tricyclics may pose similar risks. The risk of sudden death is also increased when heart rate variability is reduced, and the tricyclics reduce heart rate variability ([Roose et al. 1998](#)).

As mentioned earlier (see subsection “Attention-Deficit/Hyperactivity Disorder”), five cases of sudden death were reported in children younger than 12 years who were receiving desipramine ([Riddle et al. 1991, 1993](#)). It was suggested that the immature conduction system in some children might render them more vulnerable to the cardiac effects of desipramine. However, no cardiac abnormalities were observed in a study of 71 children with 24-hour cardiac monitoring ([Biederman et al. 1993](#)). These findings suggest that cardiac events in children are not dose dependent and that electrocardiogram monitoring is not likely to identify those at risk.

## Hepatic Effects

Acute hepatitis has been associated with use of imipramine ([Horst et al. 1980](#); [Moskovitz et al. 1982](#); [Weaver et al. 1977](#)) or desipramine ([Powell et al. 1968](#); [Price et al. 1983](#)). Mild increases in liver enzymes (less than three times normal) are not uncommon and usually can be monitored safely over a period of days or weeks. Enzyme changes do not appear to be related to drug concentrations ([Price et al. 1984](#)). Acute hepatitis is relatively uncommon but can occur. The etiology is not well established, but in some cases the condition appears to represent a hypersensitivity reaction. Tricyclic-induced acute hepatitis is characterized by very high enzyme levels (e.g., aspartate aminotransferase [AST] levels >800), which develop within days. The enzyme pattern can be either hepatocellular or cholestatic. Enzyme changes may precede clinical symptoms, especially in the hepatocellular form. If a random blood test indicates mildly elevated liver enzymes, enzyme levels can be followed for a few days. Because of the rapid rise in liver enzyme levels in acute hepatitis, that condition will become evident quickly and will be easily distinguished from mild, persistent enzyme level elevations.

Acute hepatitis is a dangerous and potentially fatal condition. If it develops, the antidepressant must be discontinued and should not be introduced again, because the next reaction may be more severe.

## Other Side Effects

Increased sweating can occur with the tricyclic compounds; occasionally, sweating can be marked. Carbohydrate craving also can occur, and when coupled with antihistaminic effects can lead to significant weight gain. Weight gain appears to be greater with the tertiary compounds than with the secondary agents. Sexual dysfunction has been described with the tricyclics but appears to be less common than with the SSRIs. This side effect appears to be associated with the more serotonergic compounds such as clomipramine. Tricyclic antidepressants can cause allergic skin rashes, which are sometimes associated with photosensitivity reactions. Various blood dyscrasias also have been reported; fortunately, these are very rare.

## Overdose

Because antidepressants are used by depressed patients who are at risk for overdose, the lethality of antidepressant drugs in overdose is of great concern. A tricyclic overdose of 10 times the total daily dosage can be fatal ([Gram 1990](#); [Rudorfer and Robins 1982](#)). Death most commonly results from cardiac arrhythmia. However, seizures, CNS depression, and respiratory depression also can occur. Although the use of tricyclics in depression has declined, amitriptyline remains widely used for other indications, such as pain. The total number of amitriptyline-associated deaths reported to U.S. poison control centers is more than twice the number of deaths associated with all other tricyclics and tetracyclics combined ([Mowry et al. 2014](#)). All of the tricyclic and tetracyclic compounds can be dangerous in overdose; however, two reports found that the ratio of deaths to number of prescriptions written was relatively low for clomipramine compared with that for other tricyclics ([Cassidy and Henry 1987](#); [Farmer and Pinder 1989](#)).

## Teratogenicity

The long history of tricyclic use without observation of birth defects argues for the safety of these agents. Of course, the patient must be informed of the possible risks and benefits of taking the drug and the risks of discontinuing treatment before making a decision. The risk of recurrence is particularly high during or following pregnancy for patients with a prior history of depression.

If tricyclics are continued during pregnancy, dosage adjustment may be required because of metabolic changes ([Altshuler and Hendrick 1996](#)). Drug withdrawal following delivery can occur in the infant and is characterized by tachypnea, cyanosis, irritability, and poor sucking reflex. Drugs in this class should be discontinued 1 week prior to delivery if possible. The tricyclics are excreted in breast milk at concentrations similar to those in plasma, but the actual quantity delivered is very small, so that drug levels in the infant are usually undetectable ([Rudorfer and Potter 1997](#); also see [Chapter 57, "Psychopharmacology During Pregnancy and Lactation"](#)).

---

## Drug-Drug Interactions

---

Both pharmacodynamic and pharmacokinetic drug interactions should be considered.

## Pharmacodynamic Interactions

Serious pharmacodynamic interactions can occur between the tricyclics and the MAOIs. The most dangerous scenario—administration of a large dose of a tricyclic to a patient who is already taking an MAOI—could result in a sudden increase in catecholamines and a potentially fatal hypertensive reaction. Tricyclics and MAOIs have been used together to treat patients with refractory depression ([Goldberg and Thornton 1978](#); [Schuckit et al. 1971](#)). When used in combination, treatment is begun with lower dosages, and either the two compounds are started together or the tricyclic is started first.

The most common pharmacodynamic interaction involving tricyclics occurs when they are added to other sedating agents, resulting in increased sedation. By blocking the norepinephrine transporters, the tricyclics block the uptake and thus interfere with the

actions of guanethidine and tyramine. Desipramine and the other tricyclics reduce the effect of clonidine.

Quinidine is an example of a drug with a potential for dynamic and kinetic interaction with tricyclics. Because the tricyclics have quinidine-like effects, the effects of tricyclics and quinidine on cardiac conduction are potentially additive. In addition, quinidine is a potent CYP2D6 isoenzyme inhibitor that can raise tricyclic levels, further adding to the problem.

## Pharmacokinetic Interactions

A number of drugs can block the metabolic pathways of the tricyclics, resulting in higher and potentially toxic blood levels of drug. Desipramine has been of particular interest because it is metabolized via the CYP2D6 isoenzyme and there are no major alternative pathways. Inhibition of CYP2D6 can result in very high desipramine plasma levels, and toxicity can occur ([Preskorn et al. 1990](#)). Quinidine, mentioned above, is a very potent CYP2D6 inhibitor. Fluoxetine and paroxetine, duloxetine, bupropion, and some antipsychotics also inhibit CYP2D6. Fluoxetine and paroxetine at usual dosages raise desipramine levels, on average, three- to fourfold in individuals who are extensive metabolizers ([Preskorn et al. 1994](#)). CYP2D6 inhibitors would be expected to block nortriptyline metabolism, but the magnitude of this interaction has not been well studied.

Because the tertiary tricyclics are metabolized by several pathways (CYP1A2, 3A4, 2C19), a selective inhibitor of one pathway would be unlikely to have a significant effect on their plasma levels. Although numerous drug interactions have been described, many are of doubtful clinical significance (for comprehensive reviews, see [Nemeroff et al. 1996](#); [Pollock 1997](#)).

Enzyme induction can also occur, which may render the tricyclic acted upon ineffective. Unlike enzyme inhibition, which occurs quickly, enzyme induction requires synthesis of new enzyme, and the full effect may take 2-3 weeks to develop. Barbiturates and carbamazepine are potent inducers of CYP3A4; induction by phenytoin appears to be less pronounced. Although CYP2D6 is a noninducible isoenzyme, phenobarbital reduces the availability of desipramine substantially. Apparently when CYP3A4 is induced, it becomes an important metabolic pathway for desipramine and the other tricyclics. In this author's experience, it can be difficult to attain an effective blood level of desipramine in the presence of a barbiturate.

Nicotine induces the CYP1A2 pathway and may lower concentrations of the tertiary tricyclics, but the secondary tricyclics (e.g., desipramine, nortriptyline) are less affected.

Acute ingestion of alcohol can reduce first-pass metabolism, resulting in higher tricyclic levels. Because tricyclic overdose is often associated with alcohol ingestion, this is an important consideration. Alternatively, chronic use of alcohol appears to induce hepatic isoenzymes and may lower tricyclic levels ([Shoaf and Linnoila 1991](#)).

The tricyclics themselves appear to be weak enzyme inhibitors, and few clinically significant interactions have been described. The tertiary tricyclics compete with warfarin for some metabolic enzymes (e.g., CYP1A2) and may raise warfarin levels.

---

## Conclusion

---

The tricyclic drugs were the mainstay of treatment for depression for three decades. Although the second-generation antidepressants appear to be better tolerated, no new

agent has been shown to be more effective than the tricyclics, and if anything, there has been concern that the new agents may be less effective. The tricyclics were “dirty” drugs; that is, they had multiple actions. Although their side effects have been emphasized, these multiple actions may contribute to their efficacy. Not only does amitriptyline block uptake of 5-HT, but its metabolite blocks uptake of norepinephrine, and in addition, amitriptyline is a 5-HT<sub>2</sub> antagonist. Furthermore, the anticholinergic effects of amitriptyline may contribute to antidepressant activity. The principal drawback of this class of agents is the risk of serious cardiac adverse effects. Tricyclics can aggravate arrhythmia in patients with preexisting conduction delay. They also may increase the risk of sudden death in children and in patients with ischemic heart disease. Moreover, a week’s supply of medication taken in overdose can be fatal. Because of these adverse effects, it is unlikely that there will be a resurgence of interest in the tricyclics. Nevertheless, the efficacy of these agents across a range of disorders, including pain, illustrates the potential advantages of antidepressant drugs that have multiple actions.

# CHAPTER 10

## Fluoxetine

Jerrold F. Rosenbaum, M.D.

Dawn F. Ionescu, M.D.

The introduction of fluoxetine as the first selective serotonin reuptake inhibitor (SSRI) approved in the United States—initially for the treatment of depression—represents an important advance in psychopharmacology and has been the catalyst for much subsequent basic and clinical research. Considerable evidence has demonstrated that fluoxetine, like other SSRIs, has a broad spectrum of clinical indications. There is a consensus, however, that the commercial success of fluoxetine (and subsequently marketed SSRIs) derived from its advantageous safety profile, which propelled the SSRIs to dominance in the antidepressant drug market. Fluoxetine, under the brand name Prozac, became a cultural icon—a symbol of the growth in antidepressant prescribing and depression recognition. Consequently, it also became a focus of controversies about rare events attributed to side effects,

such as violent acts and suicide, and a symbol of the medicalization of mental health concerns. Fluoxetine was also the first of the SSRI blockbuster drugs to become available in generic form; ironically, with decreased cost came decreased market share, likely reflecting the reduction in marketing and availability of office samples. Although SSRIs, as a class, share several common features, individual agents (such as fluoxetine) also have unique characteristics.

## History and Discovery

---

Serotonin (5-HT) is an indoleamine with wide distribution in plants, animals, and humans. Pioneering histochemistry by [Falck et al. \(1962\)](#) found that 5-HT was localized within specific neuronal pathways and cell bodies. These originate principally from two discrete nuclei: the medial and dorsal raphe. Across animal species, 5-HT innervation is widespread. Although regional variations exist, several limbic structures manifest especially high levels of 5-HT ([Amin et al. 1954](#)).

However, the 5-HT levels in the central nervous system (CNS) represent only a small fraction of the 5-HT levels in the body ([Bradley 1989](#)). Because 5-HT does not cross the blood-brain barrier, it must be synthesized locally. 5-HT is released into the synapse from the cytoplasmic and vesicular reservoirs ([Elks et al. 1979](#)). Following its release, 5-HT is principally inactivated by reuptake into nerve terminals through a sodium/potassium ( $\text{Na}^+/\text{K}^+$ ) adenosine triphosphatase (ATPase)-dependent carrier ([Shaskan and Snyder 1970](#)). The transmitter is subsequently subject to

either degradation by monoamine oxidase (MAO) or vesicular restorage. Abnormalities in central 5-HT function have been hypothesized to underlie disturbances in mood, anxiety, satiety, cognition, aggression, and sexual drives, to highlight a few. As described by [Fuller \(1985\)](#), there are several loci at which therapeutic drugs might alter 5-HT neurotransmission. The explosion of knowledge regarding the serotonergic system can largely be traced to the development of compounds, such as fluoxetine, that block the reuptake of this neurotransmitter.

---

## Structure-Activity Relations

---

Drugs that inhibit 5-HT reuptake vary in their selectivity. Despite the tendency to lump the contemporary SSRIs into the same class designation, significant structural and activity differences exist. Their chemical structures help illustrate this diversity ([Figure 10-1](#)). In contrast to paroxetine and sertraline, which exist as single isomers, fluoxetine, like citalopram, is a racemate. The family of SSRIs manifests diverse structural and activity relations. Such data are in vitro and thus subject to methodological variability ([Thomas et al. 1987](#)). Fluoxetine is less potent than paroxetine in vitro and less selective for 5-HT reuptake inhibition (relative to norepinephrine) than citalopram. However, note that in vitro potency does not necessarily equate with in vivo dosing experience, clinical efficacy, or adverse-event profile.

---

**FIGURE 10-1.** Chemical structures of selective serotonin reuptake inhibitors and selected tricyclic antidepressants.

Although the tricyclic antidepressants (TCAs), like the SSRIs, antagonize 5-HT receptors ([Dempsey et al. 2005](#); [Eisensamer et al. 2003](#)), they also exhibit inhibitory activity at other receptor targets, mediating their adverse-event profile ([Hall and Ogren 1981](#); [Snyder and Yamamura 1977](#); [U'Prichard et al. 1978](#)). These other targets include histaminergic,  $\alpha_1$ -adrenergic, and muscarinic receptors. For fluoxetine, the median inhibitory concentration ( $IC_{50}$ ) at histaminergic and adrenergic sites is in the micromolar range and thus unlikely to be of clinical significance. Activity at the muscarinic receptor is negligible for fluoxetine. [Stauderman et al. \(1992\)](#) reported that fluoxetine and paroxetine inhibit the binding of  $^3H$ -labeled nitrendipine to L-type calcium channels; however, this was at concentrations that were probably in excess of those achieved during in vivo treatment of depression.

In summary, in vitro radioligand-binding techniques showed that fluoxetine had a lower probability of many of the troublesome side effects associated with TCAs and was relatively selective in its 5-HT reuptake inhibition.

---

## Pharmacological Profile

---

### Serotonin

The action of any SSRI extends beyond the inhibition of 5-HT reuptake. At least 14 different 5-HT receptor subtypes reside at pre- and postsynaptic locations ([Fuller 1996](#)). Serotonin<sub>1A</sub> (5-HT<sub>1A</sub>) binding sites include both somatodendritic and presynaptic auto-receptors (which inhibit 5-HT firing) and postsynaptic receptors. The latter are predominantly hippocampal, and their sensitivity is increased after chronic antidepressant exposure ([Aghajanian et al. 1988](#); [Castro et al. 2003](#)).

After chronic administration, many antidepressants downregulate or reduce the density of serotonin<sub>2</sub> (5-HT<sub>2</sub>) binding sites in rat frontal cortex ([Peroutka and Snyder 1980](#)). Some, but not all, SSRIs have been associated with this effect ([Fraser et al. 1988](#)), and fluoxetine has been demonstrated to normalize 5-HT<sub>1A</sub> density in rats ([Sodero et al. 2006](#)). SSRIs, as a drug class, have been reported to normalize both 5-HT<sub>1A</sub> and 5-HT<sub>2</sub> receptor density among patients with depression ([Leonard 1992](#)).

The mechanisms by which fluoxetine and other SSRIs interact with the human serotonin transporter (SERT) are not fully understood. Some evidence suggests that fluoxetine's effect on SERT is partially based on SERT promoter polymorphism; it can lead to increased or decreased SERT expression, depending on an individual's genotype ([Little et al. 2006](#)). Further studies have shown that SERT may also be inhibited at the posttranslational stage, likely through multiple binding sites on the SERT molecule itself ([Henry et al. 2006](#); [Iceta et al. 2007](#)).

Fluoxetine transiently inhibits dorsal raphe firing, decreases terminal autoreceptor function, and ultimately increases net 5-HT synaptic transmission within CA3 pyramidal cells in the hippocampus ([Blier et al. 1988](#)).

Electrophysiological studies indicate that most antidepressants enhance net 5-HT transmission after chronic administration ([Blier et al. 1990](#)), albeit at different loci: the TCAs via enhanced sensitivity of postsynaptic 5-HT<sub>1A</sub> receptors, and the SSRIs (and MAO inhibitors [MAOIs]) via reduced sensitivity of somatodendritic (5-HT<sub>1A</sub>) and terminal (serotonin<sub>1D</sub> [5-HT<sub>1D</sub>]) autoreceptors. SSRIs and TCAs also exert an inhibitory effect on serotonin<sub>3</sub> (5-HT<sub>3</sub>) receptors in a noncompetitive fashion ([Eisensamer et al. 2003](#)). These observations of different mechanisms may help to explain why certain depressive symptoms that do not respond to one class of antidepressant will respond to another class and may also explain the enhanced response reported when combinations of antidepressant agents are used.

## Norepinephrine

Chronic administration of most somatic treatments for depression downregulates or reduces the density of  $\beta$ -adrenergic binding sites in the brain ([Bergstrom and Kellar 1979](#)). These treatments include traditional norepinephrine-specific and mixed uptake inhibitors ([Charney et al. 1981](#)). However, results with the SSRIs have been less consistent ([Johnson 1991](#)). Despite its in vitro 5-HT selectivity, fluoxetine has been observed, with autoradiography, to induce  $\beta$ -adrenergic receptor downregulation. It has also been shown in at least one study to increase extracellular norepinephrine concentrations in rat prefrontal cortex after acute systemic administration; this effect was not observed with other SSRIs tested ([Bymaster et al. 2002](#)). Fluoxetine has also

been demonstrated to potentiate the noradrenergic effects of bupropion ([Li et al. 2002](#)).

Most studies with SSRIs have not shown a consistent change in  $\beta$ -adrenergic binding or  $\beta$ -adrenergic-stimulated cyclic adenosine monophosphate (cAMP) production. However, [Baron et al. \(1988\)](#) reported that fluoxetine, when it was coadministered with desipramine, augmented the reduction in cortical  $\beta$ -adrenergic receptors expected with desipramine alone. In contrast, investigations with fluvoxamine, paroxetine, and citalopram have not yielded consistent results. In general, the greater the 5-HT selectivity of a compound, the less in vitro evidence for  $\beta$ -adrenergic downregulation has been seen. Thus,  $\beta$ -adrenergic downregulation may not be essential for clinical efficacy.

Current data do not support a significant effect on  $\alpha$ -adrenergic receptor affinity or density by the SSRIs. Studies using radiolabeling to investigate fluoxetine ([Wong et al. 1985](#)) have shown relative inactivity at this site. Fluoxetine has been reported to reduce desipramine-induced release of growth hormone after 4 weeks of treatment ([O'Flynn et al. 1991](#)). This effect suggests possible indirect activity at the  $\alpha_2$ -adrenergic receptor.

In summary, although relative differences in adrenoceptor affinity exist across the SSRI class, and fluoxetine may have more adrenergic activity than some of the other SSRIs, the clinical significance of these differences appears to be negligible.

## Dopamine

Animal studies provide evidence that the serotonergic system may exert tonic inhibition on the central dopaminergic system. Serotonin has also been shown to decrease the generation of dopaminergic cells from mesencephalic precursors in rats, an effect mediated by serotonin<sub>4</sub> (5-HT<sub>4</sub>) and serotonin<sub>7</sub> (5-HT<sub>7</sub>) receptors found on glial cells ([Parga et al. 2007](#)). Thus, fluoxetine might diminish dopaminergic transmission, consistent with anecdotes of extrapyramidal side effects (EPS) occurring during fluoxetine therapy ([Bouchard et al. 1989](#)). 5-HT agonists, however, also exert a facilitatory influence on dopamine release ([Benloucif and Galloway 1991](#)), which can be antagonized by the 5-HT<sub>1</sub> blocker pindolol, and evidence suggests that SSRIs may actually sensitize mesolimbic dopamine receptors ([Arnt et al. 1984a, 1984b](#)). Furthermore, repeated administration of fluoxetine, citalopram, or paroxetine to rats increased spontaneous dopaminergic neuronal activity ([Sekine et al. 2007](#)), and chronic fluoxetine treatment also increased brain-derived neurotrophic factor (BDNF) expression within rat dopaminergic regions ([Molteni et al. 2006](#)).

## Summary of Neurotransmitter Effects

Fluoxetine enhances central 5-HT transmission through increased output and/or increased postsynaptic receptor sensitivity ([Blier et al. 1987](#)). Fluoxetine's overall effects on the noradrenergic and dopaminergic systems are less straightforward and are also less likely to play a role in the drug's antidepressant effects. However, such changes

alone, in any of the neurotransmitter systems, do not guarantee a clinically meaningful response ([Charney et al. 1984](#)). A change in baseline 5-HT function or a “permissive” set of interactions with other collocated neurotransmitter receptors is likely involved in the highly individualized responses in patients with depression.

---

## Pharmacokinetics and Disposition

---

Considerable pharmacokinetic variability exists within the SSRI class ([Leonard 1992](#)). Of particular note, discussion of drug half-life must also include consideration of the presence or absence of active metabolites. Fluoxetine is extensively metabolized by the liver’s cytochrome P450 (CYP) system to its active metabolite, norfluoxetine. Fluoxetine is a potent CYP2D6 inhibitor, and norfluoxetine has a moderate inhibitory effect on CYP3A4 ([Hemeryck and Belpaire 2002](#)). The elimination half-life of norfluoxetine (4–16 days) is significantly longer than that of fluoxetine (4–6 days); in fact, norfluoxetine’s half-life is the longest of any of the SSRIs or their active metabolites. Half-life is not significantly affected by hemodialysis or renal impairment ([Aronoff et al. 1984](#)).

The relatively long half-life of fluoxetine confers greater protection from the discontinuation syndrome that is associated with abrupt discontinuation or noncompliance related to interruption of treatment than more rapidly cleared SSRIs. Conversely, more prolonged vigilance for drug-drug interactions following discontinuation is required for fluoxetine; for example, a 5-week washout

from fluoxetine is recommended before initiating an MAOI (Ciraulo and Shader 1990; Lane and Baldwin 1997). Variability in drug half-life is associated with a range in time to steady-state plasma concentrations, which does not clearly predict or correlate with onset of antidepressant activity.

---

## Mechanism of Action

---

In the absence of pharmacological manipulation, the reuptake of 5-HT into the presynaptic nerve terminal typically leads to its inactivation. Fluoxetine, through blockade of the reuptake process, acutely enhances serotonergic neurotransmission by permitting 5-HT to act for an extended period of time at synaptic binding sites. A net result is an acute increase in synaptic 5-HT. One difference separating SSRIs from direct-acting agonists is that SSRIs are dependent on neuronal release of 5-HT for their action—that is, SSRIs can be considered augmenters of basal physiological signals, but they are not direct stimulators of postsynaptic receptor function, and they are dependent on presynaptic neuronal integrity. These pharmacodynamic features might explain SSRI nonresponse. If the release of 5-HT from presynaptic neuronal storage sites is substantially compromised and, in turn, if net synaptic 5-HT concentration is negligible, a clinically meaningful response to an SSRI would not be expected.

Serotonin receptors also include a family of presynaptic autoreceptors that suppresses the further release of 5-HT, thus limiting the degree of postsynaptic receptor

stimulation that can be achieved. [de Montigny et al. \(1989\)](#) investigated the mechanism of action of several SSRIs and suggested that the enhanced efficacy of serotonergic synaptic transmission is not the result of increased postsynaptic sensitivity. Rather, longer-term SSRI treatment induced a desensitization of somatodendritic and terminal 5-HT autoreceptors. This desensitization would permit 5-HT neurons to reestablish a normal rate of firing, despite sustained reuptake blockade. These neurons could then release a greater amount of 5-HT (per impulse) into the synaptic cleft. This modification reportedly occurs over a time course that is compatible with the antidepressant response.

## Indications and Efficacy

---

The U.S. Food and Drug Administration (FDA)-labeled indications for fluoxetine are major depressive disorder, obsessive-compulsive disorder (OCD), panic disorder, bulimia nervosa, and premenstrual dysphoric disorder (PMDD). We will review these as well as some other disorders for which fluoxetine is commonly used.

### Major Depressive Disorder

Placebo-controlled, double-blind trials have established the superiority of fluoxetine over placebo in depression ([Kasper et al. 1992](#)). Statistically significant reductions from baseline in the Hamilton Rating Scale for Depression (Ham-D; [Hamilton 1960](#)) score have been seen as early as the second week of treatment; however, the rate and quality of

response to any SSRI are highly individualized (range, 10–42 days). Overall, the efficacy of fluoxetine has been found to be comparable to or slightly better than that of the conventional TCAs ([Cipriani et al. 2005](#); [Wernicke et al. 1987](#)) and comparable to that of venlafaxine ([Nemeroff et al. 2007](#); [Schatzberg and Roose 2006](#)). Notwithstanding, in a survey of 439 clinicians, about one-quarter indicated that they believed SSRIs to be the most efficacious antidepressant class, despite a lack of clear empirical evidence ([Petersen et al. 2002](#)). Within the class of SSRIs, there is no clear and consistent evidence for superior effectiveness of one agent over another in primary care settings ([Kroenke et al. 2001](#)).

In general, the range for dose titration with most SSRIs is relatively narrow, and higher dosages are more often associated with increased adverse events ([Altamura et al. 1988](#); [Amin et al. 1989](#)). [Schweizer et al. \(1990\)](#) reported that in a study of 108 subjects treated with 20 mg of fluoxetine for 3 weeks and then randomly assigned to receive either 20 mg or 60 mg for another 5 weeks, both groups did equally well after 8 weeks.

However, early implementation of high-dose therapy may be appropriate in some circumstances. Conversion of nonresponders by prescribing at the higher end of the dose range has been described with fluoxetine ([Fava et al. 1992](#)). Unfortunately, plasma-level studies have contributed little to the understanding of the dose–response relationship. Most studies have failed to confirm any relationship between clinical response and plasma concentration with fluoxetine ([Kelly et al. 1989](#)). This suggests that synaptic concentrations and/or pharmacodynamic effects are not accurately reflected by plasma levels.

Continued efficacy of fluoxetine during maintenance therapy has been established in several trials ([Danion 1989](#); [Dufour 1987](#); [Ferrey et al. 1989](#); [Montgomery et al. 1988](#); [Reimherr et al. 1998](#)). One trial reported a recurrence in 54 of 94 placebo subjects (57%) versus 23 of 88 fluoxetine-maintained subjects (26%) ( $P < 0.0001$ ) who had at least 4.5 months of recovery before randomization ([Montgomery et al. 1988](#)). Study participants were required to have had at least two previous episodes.

Although fluoxetine is perceived as “activating,” considerable evidence supports its utility in depression with anxious features. [Montgomery \(1989a\)](#) conducted a meta-analysis of several fluoxetine trials that indicated efficacy in depression featuring anxiety and psychomotor agitation. Similar findings have been reported by [Jouvent et al. \(1989\)](#) and [Beasley et al. \(1991\)](#).

In an attempt to improve compliance with long-term antidepressant treatment, a once-weekly formulation of fluoxetine was developed and approved. Although the concept appears reasonable and the preparation, a once-weekly enteric-coated 90-mg tablet, is safe and efficacious for continuation treatment ([Schmidt et al. 2000](#)), this formulation has not attracted widespread use, which suggests that a once-daily formulation may be convenient enough for most patients.

## Obsessive-Compulsive Disorder

Clomipramine, a potent inhibitor of both 5-HT and norepinephrine reuptake, was observed more than 30 years ago to reduce obsessive-compulsive symptoms ([Van Renynghe de Voxvrie 1968](#)). The superior benefit of this

potent serotonergic TCA over desipramine represents a cornerstone in the 5-HT hypothesis of OCD ([Benkelfat et al. 1989](#)). Fluoxetine has been shown to be effective in OCD independent of a patient's comorbid mood status ([Jenike et al. 1989](#)). Patients who have OCD may require higher doses of medication and longer treatment periods than do patients with depression to determine response. Currently, clomipramine and the SSRIs are considered to be the first-line agents for treatment of OCD ([Kaplan and Hollander 2003](#)).

Because OCD is a chronic disorder, prolonged fluoxetine therapy may be necessary. In patients whose symptoms have been minimally or only moderately reduced with SSRI treatment, numerous augmentation strategies have been proposed and include tryptophan, fenfluramine, lithium, buspirone, trazodone, or an antipsychotic (see [Goodman et al. 1992](#)). In addition, fluoxetine has shown efficacy in children and adolescents with OCD ([Geller et al. 2001](#)). In so-called OCD spectrum disorders (now grouped, in DSM-5 [[American Psychiatric Association 2013](#)], under obsessive-compulsive and related disorders), such as skin picking ([Bloch et al. 2001](#)) and body dysmorphic disorder ([Phillips et al. 2002](#)), controlled trials also indicate efficacy for fluoxetine.

## Panic Disorder

SSRIs are the drugs of choice in the prevention of panic attacks and in the treatment of panic disorder. Positive results from double-blind, placebo-controlled trials in patients with panic disorder are available for fluoxetine ([Michelson et al. 2001](#)). In general, patients with panic

disorder need a low initial dose of fluoxetine (e.g., 10 mg); however, often usual antidepressant dosing for optimal response (e.g., 20–80 mg) is required. The initial low dose serves to minimize early side effects in anxious patients who are particularly sensitive to somatic symptoms of anxiety, and it sets the stage for long-term compliance. The recurrent and chronic nature of panic disorder requires individual medication regimens that may include multiple agents as well as variable dosages.

## Eating Disorders

Manipulation of central 5-HT results in significantly altered feeding behaviors (e.g., an increased satiety response) ([Carruba et al. 1986](#)). [Blundell \(1986\)](#) reported that pharmacological enhancement of 5-HT reduced meal size, rate of eating, and body weight. The predominant locus of this 5-HT effect is likely within the hypothalamus and may be mediated through gene expression of neuropeptide Y (NPY) and pro-opiomelanocortin (POMC) ([Myung et al. 2005](#)). In general, the ability of an antidepressant to diminish appetite and, in turn, to reduce weight is related to its ability to block 5-HT uptake ([Angel et al. 1988](#)).

### **Bulimia Nervosa**

Agents with at least some degree of 5-HT uptake inhibition have been useful in bulimia nervosa (see [Brewerton et al. 1990](#)). Clinical trials with fluoxetine have found a positive treatment effect on binge eating and purging behaviors ([Goldstein et al. 1995](#)). In a large placebo-controlled trial, [Enas et al. \(1989\)](#) studied dosing of 20 mg versus 60 mg of fluoxetine in 382 female outpatients with bulimia. A clinical

benefit was observed in binge frequency, purging, mood, and carbohydrate craving. In a smaller study of 91 female patients in a primary care setting, women assigned to receive fluoxetine kept more physician appointments, exhibited greater reductions in binge eating and vomiting, and had a greater improvement in psychological symptoms than those assigned to receive placebo ([Walsh et al. 2004](#)). Continued treatment with fluoxetine is associated with improvement and decreased risk of relapse ([Romano et al. 2002](#)).

## **Anorexia Nervosa**

Pharmacological trials with SSRIs in patients with anorexia nervosa have been relatively sparse. [Kaye et al. \(1991\)](#) suggested that fluoxetine may help maintain body weight in patients with anorexia nervosa who have gained weight. This group also completed a similar study with fluoxetine under controlled conditions, suggesting some benefit for fluoxetine in improving outcome and preventing relapse ([Kaye et al. 2001](#)). On the other hand, [Walsh et al. \(2006\)](#) found no benefit for continued treatment with fluoxetine after weight restoration in a randomized, double-blind, placebo-controlled trial of 93 patients. Efficacy of SSRIs has been linked to the food obsessions of many patients with eating disorders.

## **Premenstrual Dysphoric Disorder**

Several randomized, blinded, placebo-controlled trials that used various diagnostic criteria and outcome measures have established the efficacy and tolerability of fluoxetine in the treatment of PMDD ([Menkes et al. 1993](#); [Pearlstein et](#)

al. 1997; Steiner et al. 1995; Su et al. 1993, 1997; Wood et al. 1992). In the largest study, 313 women with DSM-III-R late luteal phase dysphoric disorder ([American Psychiatric Association 1987](#)) received 20 mg of fluoxetine, 60 mg of fluoxetine, or placebo daily for six menstrual cycles after a two-cycle placebo washout period ([Steiner et al. 1995](#)). One hundred eighty women completed the study. Both doses of fluoxetine were superior to placebo, beginning at the first menstrual cycle and continuing throughout the six cycles. More patients treated with 60 mg of fluoxetine discontinued because of adverse events than did patients treated with 20 mg of fluoxetine or placebo. More patients treated with placebo discontinued because of lack of response than did patients treated with either fluoxetine dose. In a subsequent study of 34 women, fluoxetine was significantly superior to bupropion and placebo in treating PMDD ([Pearlstein et al. 1997](#)).

## Anger and Aggression

Diminished serotonergic activity has been implicated in the personality features of impulsivity, anger, hostility, and aggression ([Coccaro et al. 1989](#)). These clinical attributes best associate with DSM-IV ([American Psychiatric Association 1994](#)) Cluster B personality disorders. Fluoxetine reduced impulsivity in small groups of patients with borderline personality disorder ([Cornelius et al. 1991](#); [Norden 1989](#)). Fluoxetine significantly reduced anger attacks in patients with and without depression ([Fava et al. 1991, 1993, 1996](#); [Rubey et al. 1996](#); [Salzman et al. 1995](#)).

# Posttraumatic Stress Disorder

Fluoxetine significantly reduced symptoms of posttraumatic stress disorder (PTSD), compared with placebo, in 64 patients (veterans and nonveterans), as measured by the Clinician-Administered PTSD Scale (CAPS; [van der Kolk et al. 1994](#)). It also showed efficacy by week 6 in a large double-blind, placebo-controlled trial ([Martenyi et al. 2002](#)).

## Premature (Early) Ejaculation

SSRIs, including fluoxetine, are effective in the treatment of premature ejaculation, although increased latency to ejaculation is highest with paroxetine ([Waldinger et al. 1998](#)). In a 1-year follow-up study, patients treated with fluoxetine (20 mg/day or less) in combination with sexual behavior therapy reported significant improvement in ejaculation latency ([Graziottin et al. 1996](#)). Another study demonstrated efficacy from a weekly fluoxetine dose of 90 mg ([Manasia et al. 2003](#)). Clear-cut dosing recommendations have not been clarified, however, and titration (upward or downward) may be necessary.

## Pain Syndromes

Fluoxetine has shown efficacy in reducing pain associated with diabetic neuropathy ([Max et al. 1992](#)). Fluoxetine (20 mg/day) improved scores on measures of pain and discomfort in subjects with fibromyalgia, compared with subjects on placebo ([Arnold et al. 2002](#); [Goldenberg et al. 1996](#)). The effect of fluoxetine combined with amitriptyline was superior to the effect of either agent used alone.

Fluoxetine reduced the number of attacks in patients with migraine headaches ([Saper et al. 1994](#)). More recent work has demonstrated that antidepressants that also affect the norepinephrine system (i.e., serotonin-norepinephrine reuptake inhibitors [SNRIs]) are more effective than the SSRIs in treating neuropathic pain ([Mochizuki 2004](#); [Pedersen et al. 2005](#)). In fact, the SNRI duloxetine has received FDA approval for the treatment of neuropathic pain.

## Alcohol Use Disorder

A substantial amount of evidence supports a 5-HT dysfunction in alcohol abuse and dependence. Animal studies have shown that increased 5-HT levels reduce alcohol consumption ([Farren 1995](#)). For example, [Murphy et al. \(1988\)](#) reported beneficial effects with fluoxetine and fluvoxamine in reducing alcohol intake in a rat model.

Although results are not consistent, some clinical trials with SSRIs have reported reduced alcohol consumption in patients with and without depression, in contrast to patients treated with TCAs, which have less robust efficacy ([Cornelius et al. 1997](#); [Lejoyeux 1996](#)). A precise mechanism for the role of SSRIs in the treatment of alcohol dependence is not understood. To date, the beneficial effect, if any, appears to be independent of antidepressant activity ([Naranjo et al. 1986, 1990](#)). More work is needed to determine the specific patient subpopulations that might benefit most from SSRIs (see [Gorelick 1989](#)).

From a risk-benefit assessment, it is reassuring that fluoxetine does not appear to potentiate the effects of ethanol ([Lemberger et al. 1985](#)) and does not carry a high

risk of fatal poisoning when taken in combination with alcohol ([Koski et al. 2005](#)). SSRIs may help selected patients with alcohol dependence in recovery when these drugs are used as part of a multifaceted treatment program.

## Obesity

SSRIs have been extensively investigated for an effect on food consumption. This interest stems from evidence that perturbation of 5-HT receptors modifies animal feeding behavior ([Garattini et al. 1986](#)). This modification appears to be independent of a local gastrointestinal effect (e.g., the perception of nausea). 5-HT innervation to the hypothalamus influences satiety and may selectively affect carbohydrate consumption ([Wurtman et al. 1981](#)). In one large trial, 458 patients were treated for 52 weeks with fluoxetine (60 mg/day) or placebo ([Goldstein et al. 1994](#)). Weight loss was significantly greater in the fluoxetine-treated group at 28 weeks, but not at 52 weeks. Long-term benefits may be better sustained when fluoxetine is combined with behavior modification ([Marcus et al. 1990](#)).

The broad involvement of the serotonergic system in modulating behavior and cognition supports the wide potential utility of SSRIs.

## Other Medical Conditions

Fluoxetine has been evaluated and observed to be efficacious in a variety of conditions, including poststroke depression and motor dysfunction, fibromyalgia, chronic pain, migraine, hot flashes in menopause, repetitions and

compulsions in autism spectrum disorder, and depression in cancer patients. It has also proved useful in some patients with chronic fatigue syndrome. Interestingly, fluoxetine also appears to have antiviral properties ([Zuo et al. 2012](#)).

---

## Side Effects and Toxicology

---

Safety and a favorable side-effect profile, as well as the lack of multiple receptor affinity that mediates adverse events associated with TCAs, distinguish fluoxetine and other SSRIs from TCAs. Medications in the SSRI class generally have similar side-effect profiles.

For most patients, SSRIs are better tolerated than TCAs, based on the number of early trial discontinuations attributable to an adverse event (see [Boyer and Feighner 1991](#)). In general, for three-arm trials, the incidence of early discontinuation due to an adverse event was 5%–10% for placebo, 10%–20% for SSRIs, and 30%–35% for TCAs. The SSRIs, presumably by enhancement of 5-HT within the CNS, may induce agitation, anxiety, sleep disturbance, tremor, sexual dysfunction (primarily anorgasmia), or headache. Baseline clinical features do not appear to predispose patients to these adverse events ([Montgomery 1989b](#)). Although CNS adverse events may occur with SSRIs, [Kerr et al. \(1991\)](#) suggested that these drugs have a more favorable profile of behavioral toxicity overall than do conventional TCAs.

Because the enteric nervous system is richly innervated by 5-HT, adverse events may include altered gastrointestinal motility and nausea. Certain autonomic adverse events, including dry mouth, sweating, and weight

change, also occur. Furthermore, the use of SSRIs (including fluoxetine) during the perioperative period has been associated with a higher risk of adverse events, particularly bleeding events; however, the extent to which patient factors (e.g., medical illness) as opposed to SSRIs themselves are responsible for the elevated risks remains unknown ([Auerbach et al. 2013](#)). Fluoxetine decreases rapid eye movement (REM) and increases non-rapid eye movement (NREM) sleep at dosage ranges of 5–40 mg/kg in rodent models ([Gao et al. 1992](#)). This is a common property of many antidepressant medications. Of interest, fluoxetine induces higher rates of sedation as dosages are increased.

As was discussed earlier in this chapter (see section “Summary of Neurotransmitter Effects”), fluoxetine is unlikely to alter dopamine function; nonetheless, some side effects, such as hyperprolactinemia, extrapyramidal symptoms, sexual and cognitive dysfunction, galactorrhea, mammary hypertrophy, and gynecomastia, have been attributed to SSRI effects on the dopaminergic system ([Damsa et al. 2004](#)). Anecdotal reports of EPS ([Meltzer et al. 1979](#)) associated with SSRIs are not more frequent than those reported historically with TCAs ([Fann et al. 1976](#); [Zubenko et al. 1987](#)), MAOIs ([Teusink et al. 1984](#)), or trazodone ([Papini et al. 1982](#)). Very rare events, including arthralgia, lymphadenopathy, syndrome of inappropriate antidiuretic hormone (SIADH) secretion, agranulocytosis, and hypoglycemia, have been reported during clinical trials or postmarketing surveillance; however, causality typically is uncertain.

One additional rare and life-threatening event associated with all SSRIs (and more prominently, their interaction with MAOIs or other 5-HT enhancers) is the central 5-HT syndrome. This phenomenon appears to represent an

overactivation of central 5-HT receptors and may manifest with features such as abdominal pain, diarrhea, sweating, fever, tachycardia, elevated blood pressure, altered mental state (e.g., delirium), myoclonus, increased motor activity, irritability, hostility, and mood change. Severe manifestations of this syndrome can induce hyperpyrexia, cardiovascular shock, or death. When a switch is being made from an SSRI to an MAOI, drug half-life (and that of any active metabolite, where applicable) should serve as a guide to the length of the washout period. A standard recommendation is to wait at least five times the half-life of the SSRI or its metabolite, whichever is longer, before administering the next serotonergic agent (for a review, see [Lane and Baldwin 1997](#)). For fluoxetine, this means a minimum 5-week washout period.

Tolerance to an adverse event may change with dose and/or length of exposure; higher doses are typically associated with higher rates of adverse events ([Bressa et al. 1989](#)). Many events, such as activation, are transient, usually beginning early in the course of therapy and then remitting ([Beasley et al. 1991](#)). Comparisons between A.M. and P.M. administration did not identify differences in efficacy ([Usher et al. 1991](#)). Individual patient differences suggest the need for some flexibility in dosing schedules. TCAs behave like type IA antiarrhythmics; therefore, in a dose-dependent fashion, they may retard His-Purkinje conduction. SSRIs are essentially devoid of this property. In clinical trials, the incidence of increased heart rate or conduction disturbance has been very low with fluoxetine ([Fisch 1985](#)). For a review of the relative side-effect profiles of TCAs and SSRIs, see the article by [Brambilla et al. \(2005\)](#).

## Specific Issues

---

### Suicidality

Evidence implicating 5-HT in suicide or violence is compelling. Reduced cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) concentrations correlate highly with completed suicides in patients with depression (Edman et al. 1986; Ninan et al. 1984). In vitro binding assays have shown an increased density ( $B_{\max}$ ) of 5-HT<sub>2</sub> receptors in individuals with depression and suicidal tendencies (Pandey et al. 1990). Both observations are consistent with a relative state of 5-HT depletion among subjects with suicidal tendencies. The American College of Neuropsychopharmacology (1992) reviewed evidence showing that antidepressants result in substantial improvement or remission of suicidal ideation and impulses in the vast majority of patients; SSRIs were thought to potentially “carry a lower risk for suicide than older tricyclic antidepressants” (p. 181) when taken in overdose. Furthermore, the task force stated that no evidence indicated that SSRIs triggered emergent suicidal ideation above base rates associated with depression. In addition, Warshaw and Keller (1996) determined that fluoxetine use did not increase the rate of suicide in a group of 654 patients with anxiety disorders. In a large retrospective review of patients receiving one or more of 10 antidepressants (including fluoxetine), Jick et al. (1995) concluded that the risk for suicide was similar among all agents.

Concern about suicidality surged in 2003 after the industry alerted the FDA that there might be an increased risk of suicide-related adverse events in children being treated with paroxetine. The FDA's review of available data found that approximately 4% of children taking SSRI medications reported or exhibited suicidal thinking or behavior (including suicide attempts)—twice the rate of those taking placebo. No completed suicides occurred among nearly 2,200 children treated with SSRIs, however.

The FDA's review was followed by a number of other studies examining this issue, including a meta-analysis of 24 pediatric trials of nine antidepressant drugs by [Hammad et al. \(2006\)](#). These authors found a modestly increased risk of suicidality (risk ratio=1.66) for SSRIs in depression trials (95% confidence interval=1.02-2.68). This risk must be balanced against the benefit—in the form of general improvement in mood and overall functioning—experienced by most depressed patients when they are placed on antidepressant therapy. In most cases, the therapeutic benefit of SSRIs will outweigh the risk of increased suicidal thoughts or behaviors ([Bridge et al. 2007](#)).

## Black Box Warning

On March 22, 2004, the FDA issued a public health advisory warning of the risk of worsened depression and suicidality in children and adolescents being treated with antidepressant medications. This was followed by placement of a black box warning on the packaging of all antidepressant medications, revised in 2006 to include adults through age 25 years (for the full text of the 2007 revision, see

<http://www.fda.gov/downloads/drugs/drugsafety/informationbydrugclass/ucm173233.pdf>). After the black box warning was placed, prescriptions for antidepressants went down, and suicide attempts in children and adolescents increased. After antidepressant prescriptions dropped, suicide attempts increased by 22% in adolescents and by 34% in young adults (Lu et al. 2014).

## Use in Pregnancy and Lactation

Given the widespread use of SSRIs and the high prevalence of mood disorders during the childbearing years, it is likely that these agents are being used during pregnancy and breast-feeding. Published information about the use and safety of SSRIs in this special population is greatest for fluoxetine. Goldstein et al. (1997) evaluated the outcomes of 796 prospectively identified pregnancies with confirmed first-trimester exposure to fluoxetine. Historical reports of newborn surveys were used for comparison. Abnormalities were observed in 5% of the fluoxetine-exposed newborns, which was consistent with rates in historical controls. A review of the literature showed a statistically increased risk of persistent pulmonary hypertension of the newborn for infants exposed to SSRIs in late pregnancy, although clinically the absolute risk was low (Grigoriadis et al. 2014). A longitudinal observational study found no differences in growth variables (weight, length, head circumference) from birth to 12 months of age between infants exposed to SSRIs and those not exposed (Wisner et al. 2013). Pregnancy outcomes and follow-up cognitive and behavioral assessments for 135 children exposed in utero to a TCA or fluoxetine (55 infants) were compared with those for

children in a control group of mother–infant pairs ([Nulman et al. 1997](#)). The incidence of major malformations and perinatal complications was similar among the three groups. No statistically significant differences in mean global intelligence quotient (IQ) scores or language development were found in the children of mothers who received a TCA or fluoxetine compared with the children of control mothers. There were also no differences among the groups on several behavioral assessments. The results of children exposed during the first trimester were not different from those of children exposed throughout the pregnancy. Prospectively derived data are not available for paroxetine, sertraline, fluvoxamine, or citalopram. A recent study failed to find a significant association between risk of autism spectrum disorders in offspring and maternal use of SSRIs—including fluoxetine—during pregnancy ([Hviid et al. 2013](#)).

Fluoxetine is secreted into breast milk ([Hendrick et al. 2001](#)). The implications of this minimal exposure are unclear, but one naturalistic study ([Taddio et al. 1996](#)) and two case reports ([Burch and Wells 1992](#); [Isenberg 1990](#)), involving a total of 13 infants, noted no adverse effects in these infants during the short-term study periods. One case report did describe adverse events in a breast-fed infant whose mother was taking fluoxetine ([Lester et al. 1993](#)).

## SSRI Discontinuation Syndrome

Discontinuation symptoms have been described with several classes of antidepressants, including TCAs and MAOIs. SSRI discontinuation symptoms have been reported most frequently with paroxetine (short elimination half-life

and no active metabolite) and least frequently with fluoxetine (long elimination half-lives of parent compound and active metabolite) ([Haddad 1997](#); [Stahl et al. 1997](#)). SSRIs are not drugs of abuse; when these agents are discontinued, patients show neither the characteristic abstinence syndrome of CNS-depressant withdrawal nor drug-seeking behavior. The most common physical symptoms are dizziness, nausea and vomiting, fatigue, lethargy, flulike symptoms (e.g., aches and chills), and sensory and sleep disturbances. The psychological symptoms most commonly reported are anxiety, irritability, and crying spells. For most patients, the discontinuation symptoms are different from the adverse effects that they may have experienced while taking an SSRI. Discontinuation symptoms most often emerge within 1-3 days ([Schatzberg et al. 1997](#)).

Until recently, most information about SSRI discontinuation syndrome came from case reports or retrospective analyses. [Rosenbaum et al. \(1998\)](#) compared the effects of a 5- to 8-day abrupt discontinuation period from fluoxetine, paroxetine, or sertraline in three groups of patients with depression receiving maintenance therapy. Patients from the paroxetine and sertraline groups had a significant increase in adverse events, whereas patients in the fluoxetine group experienced no increase in adverse events.

In a more extended evaluation, the effects of abrupt discontinuation of fluoxetine were studied in 195 patients with depression ([Zajacka et al. 1998](#)). Patients whose depression remitted while they were taking fluoxetine were randomly assigned to continue fluoxetine (20 mg/day) or to discontinue abruptly and begin placebo, and they were

monitored for 6 weeks. Reports of adverse events were similar for both groups.

In summary, SSRIs with short half-lives (paroxetine and fluvoxamine) and related drugs, such as venlafaxine, should be tapered. Fluoxetine does not require tapering because of its extended half-life.

## Overdose

A major advantage of SSRIs, relative to other antidepressants, has been their superior therapeutic index ([Cooper 1988](#); [Pedersen et al. 1982](#)). The number of deaths per 1 million prescriptions, across several SSRIs (0–6), is substantially lower than that for conventional TCAs (8–53) or MAOIs (0–61) ([Leonard 1992](#)).

[Borys et al. \(1992\)](#) reported on 234 cases of fluoxetine overdose (serum level=232–1,390 ng/mL) obtained in a prospective multicenter study. Fluoxetine was the sole ingested in 87 cases; in the remaining 147 cases, it was taken in combination with alcohol and/or other drugs. Common symptoms included tachycardia, sedation, tremor, nausea, and emesis. The authors concluded that the emergent symptoms were minor and of short duration; thus, aggressive supportive care “is the only intervention necessary” ([Borys et al. 1992](#), p. 115).

## Drug-Drug Interactions

---

Although the potential for significant interactions exists, SSRIs are unlikely to be associated with many of the conventional problems seen with the earlier

antidepressants. These problems include the cumulative CNS-depressant effects with alcohol, anticholinergic agents, or antihistaminic compounds. The structural differences among SSRIs offer a basis for some intraclass differences. Lithium concentrations are generally unaffected.

One potential for clinically relevant antidepressant pharmacokinetic interactions is based on the drug effect on the CYP family of enzymes ([Brøsen and Gram 1989](#)). For example, SSRIs are both substrates for and inhibitors of oxidation via CYP2D6. [Crewe et al. \(1992\)](#) ranked the potency of CYP2D6 inhibition for serotonergic antidepressants, revealing the most clinically relevant effects on 2D6 for paroxetine and fluoxetine and less relevant effects for sertraline, fluvoxamine, citalopram, clomipramine, and amitriptyline.

Through inhibition of CYP2D6, fluoxetine may elevate the concentration of concomitantly administered drugs that rely on this enzyme for metabolism. This has particular clinical relevance when the second agent has a narrow therapeutic index. Examples of such agents include flecainide, quinidine, carbamazepine, propafenone, TCAs, and several antipsychotics ([Rudorfer and Potter 1989](#)). The clinical consequence of such an interaction may either enhance or impair efficacy and/or heighten the adverse-event profile.

The data with respect to fluoxetine's inhibition of other CYP enzymes, such as 3A3/4, 2C9, and 2C19, are less consistent, but the potential for such interaction exists.

---

## Conclusion

---

Fluoxetine has been shown to be a safe and effective drug that has proved to be better tolerated than TCAs and to have a superior safety profile in overdose for patients with comorbid medical illness. Evidence suggests a broad utilitarian role for fluoxetine across a spectrum of psychopathology.

# CHAPTER 11

## Sertraline

Linda L. Carpenter, M.D.

Alan F. Schatzberg, M.D.

---

### History and Discovery

---

Research has implicated dysregulation of serotonin (5-hydroxytryptamine [5-HT]) in mood and anxiety disorders. Researchers therefore identified compounds that are selective in blocking neurotransmitter reuptake and yet have little agonist and antagonist activity at receptors thought to be associated with adverse effects. Sertraline, a naphthylamino compound that is structurally different from monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs), is a member of this class of drugs ([Guthrie 1991](#); [Heym and Koe 1988](#)).

For the 12 months ending June 2006, it was estimated that sales of sertraline (under the brand name Zoloft) in the United States exceeded \$3 billion ([Rancourt 2006](#)). In August 2006, a generic formulation of sertraline became

available in the United States, and within the first 2 weeks of its availability, the substitution rate exceeded 77% ([Block 2006](#)).

---

## Structure-Activity Relations

---

Sertraline [(+)-*cis*-(1*S*,4*S*)-4-(3,4-dichlorophenyl)-1,2,3,4-tetrahydro-*N*-methyl-1-naphthylamine] ([Figure 11-1](#)) specifically blocks the reuptake of 5-HT in the soma and terminal regions of serotonergic neurons. The ability of sertraline to inhibit 5-HT reuptake is approximately 20-fold higher than its capacity to inhibit uptake of either norepinephrine or dopamine ([Heym and Koe 1988](#)). However, sertraline is more potent at blocking dopamine receptor uptake than are other selective serotonin reuptake inhibitors (SSRIs) and TCAs ([Hiemke and Härtter 2000](#); [Richelson 1994](#)).

---

**FIGURE 11-1.** Chemical structure of sertraline.

Serotonin neurons in the midbrain raphe nuclei have inhibitory autoreceptors in both the soma (serotonin<sub>1A</sub> [5-HT<sub>1A</sub>] receptors) and terminal area (serotonin<sub>1B</sub> [5-HT<sub>1B</sub>] receptors) that are stimulated by the acute increase in 5-HT. The immediate effect of serotonin transporter (5-HTT) blockade is to increase the amount of 5-HT in axosomatic synapses and to decrease neuronal firing ([Blier 2001](#); [Blier et al. 1990](#); [Heym and Koe 1988](#)). Over several weeks, these autoreceptors are desensitized and firing rates increase.

Unlike the older TCAs, sertraline has little appreciable antagonistic effect on histamine<sub>1</sub> (H<sub>1</sub>), muscarinic, or dopamine<sub>2</sub> (D<sub>2</sub>) receptors and thus is associated with few difficulties with severe constipation, drowsiness, and dry mouth ([Hiemke and Härter 2000](#); [Richelson 1994](#)). The antagonism of  $\alpha_1$ -adrenoreceptors by sertraline is at least 10-fold more potent than that of other SSRIs ([Hiemke and Härter 2000](#)), although this antagonism does not translate into clinically meaningful hypotension or reflex tachycardia. However, there is a report suggesting that sertraline decreases sympathetic nervous system activity, a property consistent with  $\alpha$  receptor blockade ([Shores et al. 2001](#)). It is also possible that the decrease in sympathetic response is related to stimulation of the 5-HT<sub>1A</sub> receptors noted above.

Sertraline is metabolized to desmethylsertraline (see section “Pharmacokinetics and Distribution” below). This compound is approximately one-tenth as active in blocking the reuptake of 5-HT; it also lacks antidepressant activity in animal models ([Heym and Koe 1988](#)).

---

## Pharmacological Profile

---

Among the various antidepressant agents that block the 5-HTT, sertraline is second only to paroxetine in potency for 5-HT reuptake blockade, as demonstrated in animal models ([Hiemke and Härtter 2000](#); [Owens et al. 2001](#); [Richelson 1994](#)). The selectivity of sertraline for norepinephrine follows that of escitalopram ([Hiemke and Härtter 2000](#); [Owens et al. 2001](#)), although other work suggests greater selectivity for fluvoxamine than for sertraline ([Richelson 1994](#)). The relative selectivity for the 5-HTT, compared with the dopamine transporter (DAT), is lowest for sertraline ([Owens et al. 2001](#)).

Sertraline exhibits inhibitory activity on several cytochrome P450 (CYP) enzymes. The ability of the compound to slightly elevate dextromethorphan and desipramine supports modest inhibition of CYP2D6 ([Hiemke and Härtter 2000](#); [Ozdemir et al. 1998](#); [Preskorn 1996](#)). It has little appreciable inhibition of CYP1A2, even when used at higher dosages ([Ozdemir et al. 1998](#)). A very mild elevation of CYP2C9/10 substrates has been found in several studies ([Preskorn 1996](#)). Sertraline has complex effects on the CYP3A3/4 enzyme system: it initially shows slight inhibition, but it also induces this system, albeit modestly, over time ([Preskorn 1996](#)).

---

## Pharmacokinetics and Disposition

---

Sertraline is absorbed slowly via the gastrointestinal tract, with peak plasma levels occurring between 6 and 8 hours after ingestion ([Warrington 1991](#)). The delay may be the result of enterohepatic circulation ([Hiemke and Härtter](#)

2000; van Harten 1993). When sertraline is taken with food, the peak plasma level occurs earlier, at about 5.5 hours (Pfizer 2016). The medication is more than 95% protein bound; however, because it binds weakly to  $\alpha_1$ -glycoproteins, it does not cause substantial displacement of other protein-bound drugs (Preskorn 1996).

The volume of distribution ( $V_d$ ) of sertraline is large, exceeding 20 L/kg. The distribution is larger in young females than in young males (Warrington 1991). In animal models, the concentration of sertraline is 40 times higher in brain than in plasma (Hiemke and Härtter 2000).

The elimination half-life of sertraline is 26–32 hours, and steady-state levels are achieved after 7 days. Sertraline shows linear pharmacokinetics within a range of 50–200 mg/day (Warrington 1991) and does not appear to inhibit or induce its own metabolism. Peak plasma levels are somewhat lower in young males than in young females, older females, or older males (Pfizer 2016; Ronfeld et al. 1997; Warrington 1991), and the elimination rate constant is higher in young males than in young females, older females, or older males (0.031/hour in young males, 0.022/hour in young females, and 0.019/hour in older males and females). Maximal plasma concentrations of sertraline may be significantly reduced following a gastric bypass procedure (Roerig et al. 2012).

In children between the ages of 6 and 17 years, weight-corrected metabolism is more rapid. The maximum concentration and area under the curve (AUC) are 22% lower in children than in adults. Despite this relatively more efficient metabolism, the smaller body mass of most children suggests that lower dosages of sertraline should be used in pediatric populations (Pfizer 2016).

Sertraline is metabolized in the liver via oxidative metabolism; the concentration of the primary metabolite, desmethylsertraline, is up to threefold higher than that of the parent compound ([Hiemke et al. 1991](#); [Ronfeld et al. 1997](#); [Warrington 1991](#)). Desmethylsertraline levels are also lower in young males than in young females, elderly females, or elderly males. The peak concentration ( $t_{\max}$ ) of desmethylsertraline is attained more quickly in young females than in young males, older females, and older males (6 hours in young females vs. 9 hours in young males, 8 hours in older females, and 14 hours in older males) ([Warrington 1991](#)). The half-life of desmethylsertraline is 1.6–2.0 times that of the parent compound ([Warrington 1991](#)).

Whereas desmethylsertraline is the major metabolite of sertraline, other minor metabolites include a ketone and an alcohol compound ([Warrington 1991](#)). Less than 0.2% of an oral dose of sertraline is excreted unchanged in urine, whereas approximately 50% is found in feces. The enzymes involved in metabolism of sertraline to desmethylsertraline remain unclear ([Greenblatt et al. 1999](#)). Although six different CYP enzymes have the capacity to catalyze this reaction, none accounts for more than 25% of sertraline's clearance. The contribution of each CYP enzyme is dependent not only on the protein's activity on the substrate, as evidenced through in vitro models, but also on the abundance of the enzyme. Given these properties, one computer model identified 2C9 as the greatest contributor (~23%) to sertraline demethylation, with 3A4 and 2C19 each contributing about 15%, 2D6 adding 5%, and 2B6 contributing 2% to the process ([Greenblatt et al. 1999](#); [Lee et al. 1999](#)). These percentages can vary across individuals, depending on the amount of enzyme that is available or

enzyme inhibition that occurs. Because multiple CYP enzymes are involved in sertraline's metabolism, concurrent use of medications with specific CYP inhibition is unlikely to substantially impair the process ([Greenblatt et al. 1999](#)). However, increased CYP2B activity was seen in mice as a consequence of sertraline coadministration with bupropion ([Molnari et al. 2012](#)).

Patients with liver disease experience decreased sertraline metabolism ([Hiemke and Härter 2000](#)). For individuals with mild liver impairment, the half-life of the drug may be increased threefold ([Pfizer 2016](#)), and concentrations are likely to be greater in patients with severe impairment. Although renal impairment does not appreciably influence the metabolism of sertraline ([Hiemke and Härter 2000](#)), hemodialysis patients with severe end-stage renal disease do not appear to tolerate sertraline 25 mg/day without risk of significant toxicity ([Chander et al. 2011](#)).

## Mechanism of Action

---

The means by which all antidepressants exert their therapeutic action is largely unknown, although some of the properties noted above have been related to hypothetical mechanisms ([Blier 2001](#); [Blier et al. 1990](#)). As previously mentioned, the immediate effect of sertraline is to decrease neuronal firing rates. This is followed by normalization and an increase in firing rates, as autoreceptors are desensitized. As activity in the presynaptic neuron increases, noradrenergic neurons are stimulated by postsynaptic 5-HT receptors located on noradrenergic

nerve terminals, leading to eventual downregulation of  $\beta$ -adrenergic receptors, an effect produced by many, but not all, antidepressant agents ([Frazer and Scott 1994](#); [Guthrie 1991](#)).

Not inconsistent with the above are findings suggesting that SSRI treatment decreases production of 5-HT<sub>1B</sub> messenger RNA (mRNA), the message for a regulatory autoreceptor on dorsal raphe neurons that controls the amount of 5-HT released with each impulse ([Anthony et al. 2000](#)). Again, the decrease in mRNA production coincides temporally with the time frame for SSRI therapeutic effects. In addition to inhibition of 5-HT reuptake, preclinical research demonstrated that sertraline inhibits hippocampal presynaptic sodium channels to control neurotransmitter release ([Aldana and Sitges 2012](#)), and sertraline's ability to increase extracellular dopamine concentration in nucleus accumbens and striatum differentiated it from other SSRIs ([Kitaichi et al. 2010](#)).

## Indications and Efficacy

---

### Approved Clinical Indications

Sertraline is currently approved by the U.S. Food and Drug Administration (FDA) for use in the treatment of major depressive disorder (MDD), obsessive-compulsive disorder (OCD) and pediatric OCD, posttraumatic stress disorder (PTSD), panic disorder, premenstrual dysphoric disorder (PMDD), and social anxiety disorder. Some of the pivotal

studies using this compound for these indications are reviewed in the following subsections.

## **Major Depressive Disorder**

Sertraline's efficacy in the treatment of MDD was established by a number of placebo-controlled trials for acute-phase therapy ([Fabre et al. 1995](#); [Olie et al. 1997](#); [Reimherr et al. 1990](#)). In a multicenter trial, 369 patients were randomly assigned to a fixed dosage of sertraline (50 mg/day, 100 mg/day, or 200 mg/day) or placebo for 6 weeks ([Fabre et al. 1995](#)). Patients at all dosages of sertraline showed approximately equivalent improvement, which was greater than that shown with placebo for most measures.

Sertraline was compared with amitriptyline and placebo in a multicenter trial of 448 patients ([Reimherr et al. 1990](#)). Sertraline was dosed flexibly up to 200 mg/day, and amitriptyline was administered at dosages as high as 150 mg/day. Both active treatments were superior to placebo, as indicated by Hamilton Rating Scale for Depression (Ham-D) and Clinical Global Impressions (CGI) Scale scores; similarly, response rates (rates at which patients attained a 50% decrease in the Ham-D or a CGI Scale score of 1 or 2) were higher with the active treatment compared with placebo.

In a multicenter study of 235 men and 400 women with either chronic MDD (enduring at least 2 years) or MDD superimposed on DSM-IV ([American Psychiatric Association 1994](#)) dysthymic disorder, subjects were randomly assigned to 12 weeks of either sertraline or imipramine in a 2-to-1 ratio ([Kornstein et al. 2000](#)). Treatment was double-blinded, and the study medication was titrated to a flexible maximum daily dosage of 200 mg sertraline or 300 mg imipramine. Response to both drugs was similar, but

sertraline was better tolerated. Results revealed that many who benefited had not achieved response until after 8 weeks of treatment, underscoring the need for extended sertraline trials in patients with chronic depression ([Keller et al. 1998a](#)). Another interesting finding from this study is that men and women had differential response rates to sertraline and imipramine ([Kornstein et al. 2000](#)). Remission and response outcomes were combined in an intent-to-treat analysis that showed that 57% of women but only 46% of men benefited from sertraline. Among men, response was somewhat better with imipramine than with sertraline (62% and 45%, respectively). Response rates were more rapid for men assigned to imipramine and for women assigned to sertraline. Premenopausal women were more likely to respond to sertraline, whereas postmenopausal women were equally likely to respond to either agent.

Sertraline was significantly more effective than placebo in reducing depressive symptoms of postpartum depression ([Hantsoo et al. 2014](#)), particularly in women whose symptoms began within 4 weeks of giving birth. In another recent trial, a specialized cognitive-behavioral therapy (CBT) was significantly more effective than sertraline in postpartum depressed women ([Milgrom et al. 2015](#)).

Sertraline has been shown to be effective for maintenance-phase treatment, both in patients with MDD ([Doogan and Caillard 1992](#)) and in patients with chronic MDD (defined as a major depressive episode enduring at least 2 years or co-occurring with dysthymic disorder) ([Keller et al. 1998b](#)). The [Doogan and Caillard \(1992\)](#) study followed 300 patients throughout 44 weeks of double-blind, placebo-controlled maintenance therapy and found that

13% of sertraline-treated patients, compared with 46% of placebo-treated patients, experienced a relapse.

The utility of sertraline in preventing illness recurrence among chronic MDD patients who responded to acute antidepressant therapy ( $n=161$ ) was examined in the [Keller et al. \(1998b\)](#) study, in which subjects were randomly assigned to receive 52 weeks of maintenance treatment with either placebo or sertraline. More than 60% of the sample was female and had a current episode duration that exceeded 8 years. Sertraline significantly outperformed placebo on all outcome measures; 6% of sertraline-treated patients and 23% of placebo-treated patients experienced depressive episode recurrence, and clinically significant depressive symptom re-emergence was observed in 26% of sertraline-treated patients versus 50% of patients receiving placebo.

Sertraline can be used to treat MDD in special populations. In addition to the trials just described, several studies found sertraline to be at least as effective as TCAs in treating younger adults ([Cohn et al. 1990](#); [Lydiard et al. 1997](#); [Möller et al. 1998](#)) and elderly patients ([Bondareff et al. 2000](#); [Finkel et al. 1999](#); [Forlenza et al. 2001](#)) with MDD. Sertraline has been shown to be as beneficial as nortriptyline in women with postpartum MDD ([Wisner et al. 2006](#)). Furthermore, sertraline may confer a prophylactic advantage in women at high risk for developing postpartum episodes of MDD ([Wisner et al. 2004](#)), and sertraline is one of three antidepressants judged to be evidence-based choices for MDD in women who are breast feeding ([Lanza di Scalea and Wisner 2009](#)). Several trials have shown roughly equivalent efficacy for sertraline and other SSRIs ([Aguglia et al. 1993](#); [Franchini et al. 1997](#); [Nemeroff et al. 1996](#); [Newhouse et al. 2000](#); [Stahl 2000](#)); however, a

recent Cochrane Database review and meta-analysis of all randomized controlled trials of sertraline against an active antidepressant comparator concluded that sertraline was superior to other agents for the treatment of MDD in terms of both efficacy and acceptability ([Cipriani et al. 2010](#)).

## **Premenstrual Dysphoric Disorder**

In one of the first multicenter trials to test the efficacy of an antidepressant agent for PMDD, sertraline was compared with placebo ([Yonkers et al. 1997](#)). Either placebo or sertraline (at a flexible daily dosage of 50–150 mg) was given to 243 women. After three menstrual cycles of treatment, total daily rating scores had decreased by 32% and 11% in the sertraline- and placebo-treated groups, respectively. Both emotional and physical symptom clusters improved by 32% with sertraline treatment, a reduction nearly threefold higher than that seen with placebo. At the endpoint, CGI-I scores of 1 or 2 were achieved by 62% and 34% of those assigned to sertraline and placebo, respectively.

In a second multicenter trial, it was shown that sertraline treatment could be commenced halfway through the menstrual cycle (i.e., at ovulation) and still be more effective than placebo ([Halbreich et al. 2002](#)). In this three-cycle flexible-dosage study, 281 women were randomly assigned to receive daily dosages of 50–100 mg of sertraline or placebo. The responder rates in this study, after three cycles of luteal-phase treatment, were 50% and 26% for sertraline and placebo, respectively. As with the daily treatment study, functional improvement paralleled symptomatic improvement. Only 8% of the women taking sertraline and 1% of the women receiving placebo discontinued the study because of side effects. The efficacy

of this drug administration schedule for women with PMDD has the potential to revolutionize treatment approaches, because many women with PMDD prefer to avoid taking medication during nonsymptomatic periods.

A secondary analysis of data from three large federally sponsored trials ( $n=447$ ) indicated that women with premenstrual syndrome (PMS) showed positive responses to sertraline, similar to outcomes observed in women with PMDD ([Freeman et al. 2011](#)). Examination of symptom-based subtypes in that analysis revealed that predominantly psychological symptoms or mixed psychological/physical symptoms predicted better response to sertraline than did predominantly physical symptoms.

### **Social Anxiety Disorder (Social Phobia)**

Several studies have established the efficacy of sertraline in the treatment of social anxiety disorder (also known as social phobia). In one of the earliest studies ([Katzelnick et al. 1995](#)), sertraline treatment (at flexible dosages of 50–100 mg/day) produced a statistically significant improvement compared with placebo, as measured by Liebowitz Social Anxiety Scale (LSAS) scores. A large double-blind, placebo-controlled study followed more than 200 Canadian outpatients with generalized social phobia for 20 weeks, measuring response on CGI-I scores and mean reductions on the social phobia subscale of the Marks Fear Questionnaire and the Brief Social Phobia scale ([Van Ameringen et al. 2001](#)). Fifty-three percent of patients treated with sertraline, compared with only 29% of patients receiving placebo, were either much or very much improved by the study's end, as measured by CGI-I scores. When subjects who responded to sertraline were randomly assigned to continue sertraline or switch to placebo for an

additional 24 weeks, the relative risk of relapse for those who were randomly assigned to placebo was greater than 10 ([Walker et al. 2000](#)).

[Liebowitz et al. \(2003\)](#) demonstrated that sertraline produced a significant reduction in LSAS scores and resulted in a greater proportion of responders after 12 weeks of treatment (at dosages up to 200 mg/day) compared with placebo. In a placebo-controlled study that compared sertraline, exposure therapy, and combined treatment and involved more than 380 Norwegian patients with generalized social phobia, sertraline alone or in combination with exposure therapy yielded statistically significant improvements in CGI social phobia scores, whereas exposure therapy alone did not ([Blomhoff et al. 2001](#)). While not FDA approved in the pediatric population, sertraline has been well tolerated and has shown efficacy in childhood social anxiety disorder ([Compton et al. 2001](#)).

## **Panic Disorder**

Sertraline's efficacy in the treatment of panic disorder has been demonstrated in several studies. In a 12-week randomized, placebo-controlled, flexible-dose multicenter trial in outpatients with panic disorder (with and without agoraphobia) but without depression ([Pohl et al. 1998](#)), sertraline was superior to placebo on a number of efficacy measures. One hundred sixty-eight patients meeting diagnostic criteria for panic disorder without depression were randomly assigned to receive sertraline or placebo after a 2-week single-blind lead-in. The mean sertraline dosage at endpoint was 126 mg/day (SD=62 mg/day), and the reduction in frequency of panic attacks was significantly greater for the sertraline group (77% vs. 51% for the placebo group), with significantly fewer panic symptom

episodes occurring in that group. Similar results supporting sertraline's efficacy for panic disorder were reported by [Pollack et al. \(1998\)](#), who randomly assigned 178 patients to sertraline or placebo.

A fixed-dosage study of sertraline (50 mg/day, 100 mg/day, or 200 mg/day) or placebo for 12 weeks ([Londborg et al. 1998](#)) demonstrated sertraline's superiority over placebo in numerous trial outcomes, including number of panic attacks and limited-symptom attacks, severity of anticipatory anxiety, dimensional anxiety measures, and global measures of improvement. Pooled sertraline data indicated a 65% reduction in the number of panic attacks, compared with a 39% decrease in the placebo group. Effect sizes, reflecting the magnitude of difference between the two treatments, for the three different sertraline dosages tested were 0.58 (50 mg/day), 0.41 (100 mg/day), and 0.60 (200 mg/day), but response rates did not differ significantly among dosage groups. In the panic studies described above, the authors reported a low incidence of attrition secondary to sertraline adverse events, concluding that sertraline is a safe and effective treatment for patients with panic disorder. Sertraline's beneficial effects in panic disorder may be further enhanced when the drug is used in combination with self-administered CBT ([Koszycki et al. 2011](#)).

## **Obsessive-Compulsive Disorder in Adults**

Several multicenter trials found benefit for sertraline over placebo in the acute- and maintenance-phase treatment of OCD in adults. One study failed to show superiority of sertraline over placebo, perhaps because of the limited sample size ( $n=19$ ) or the treatment-resistant characteristics of the cohort ([Jenike et al. 1990](#)). Larger-

scale studies with diverse patients had differing results. By week 3 of a 12-week flexible-dose study in 167 patients ([Kronig et al. 1999](#)), sertraline (mean 165 mg/day) differentiated from placebo. At study endpoint, 41% of patients receiving sertraline and 23% of those receiving placebo had achieved a CGI-Improvement scale (CGI-I) score of 1 or 2.

A fixed-dose study ([Greist et al. 1995](#)) also found superior results with three different daily dosages (50, 100, or 200 mg) of sertraline, compared with placebo, over 1 year of treatment in a multisite trial. OCD patients ( $n=325$ ) were randomly assigned to 12 weeks of double-blind treatment after a 1-week washout period. Responders (40% of sertraline-treated patients and 26% of placebo-treated patients) were offered enrollment in an additional 40 weeks of continuation treatment. Over the 52 weeks of the study, sertraline-treated subjects demonstrated significantly greater improvement than did subjects given placebo.

Some evidence suggests that higher daily dosages of sertraline may be helpful for patients whose symptoms do not respond to standard dosages. In one study, 66 patients with OCD that was unresponsive to sertraline therapy at dosages of 200 mg/day after 16 weeks of treatment were randomly assigned to continue on the same dosage for an additional 12 weeks or to increase their dosage to 250–400 mg/day ([Ninan et al. 2006](#)). At the end of the trial, those receiving higher dosages had greater improvement in Yale-Brown Obsessive Compulsive Scale (Y-BOCS) scores, although rates of response were similar for the two groups.

Other studies supporting the utility of sertraline in OCD have included head-to-head comparisons with other antidepressants ([Bergeron et al. 2002](#); [Bisserbe et al. 1997](#); [Hoehn-Saric et al. 2000](#)). In a comparison of lower-dosage

sertraline with cognitive-behavioral group therapy, both treatments were shown to be efficacious, although OCD patients treated with group therapy had greater reductions in symptoms ([Sousa et al. 2006](#)). Continuation of CBT versus sertraline initiation in children and adolescents with OCD who had not responded to an initial trial of CBT resulted in similar efficacy ([Skarphedinsson et al. 2015](#)).

## **Obsessive-Compulsive Disorder in Children and Adolescents**

Sertraline is approved for use in children for the treatment of OCD. In a 12-week double-blind, placebo-controlled, parallel-group multicenter trial in 187 pediatric subjects (107 children ages 6–12 years, and 80 adolescents ages 13–17 years), [March et al. \(1998\)](#) found that subjects treated with sertraline (mean endpoint dosage 167 mg/day) showed significant improvement on Y-BOCS, National Institute of Mental Health—Global Obsessive-Compulsive Scale (NIMH-GOCS), and CGI-I scores, compared with subjects receiving placebo. There were few dropouts due to adverse events, and the authors concluded that sertraline is a safe, well-tolerated treatment in this age group. A subsequent study in children and adolescents treated with sertraline (50–200 mg/day) over 12 months found that many who responded to acute treatment could achieve full or partial remission status with longer-term treatment ([Wagner et al. 2003](#)).

## **Posttraumatic Stress Disorder**

Sertraline's efficacy in the treatment of PTSD is supported by two large acute-phase, double-blind, placebo-controlled multicenter studies ([Brady et al. 2000](#); [Davidson et al. 2001b](#)), a long-term treatment study ([Londborg et al.](#)

2001), and a relapse prevention trial (Davidson et al. 2001a).

In the first acute-phase trial (Davidson et al. 2001b), 208 civilian patients were randomly assigned to receive either sertraline or placebo for 12 weeks. Observed symptom reductions with active treatment were about 50% for re-experiencing/intrusion, just under 50% for avoidance/numbing, and 40% for arousal. The probability of response, defined as a CGI Scale score of 1 or 2 and a minimal 30% decrease in the Clinician-Administered PTSD Scale—Part 2 (CAPS-2), was 0.65 in sertraline-treated patients and 0.38 in placebo-treated patients at the 12-week endpoint. Approximately 40% of each group had comorbid MDD, with mean baseline 21-item Ham-D scores around 21. Of interest, there were no significant differences among groups in depression symptom severity. The second acute-phase study (Brady et al. 2000) yielded similarly positive results.

In a pediatric sample with PTSD, 10 weeks of treatment with sertraline 50–200 mg/day appeared generally safe but did not produce outcomes superior to those with placebo (Robb et al. 2010).

Whereas the overall acute-phase efficacy of sertraline for PTSD was significant for women in the large controlled studies reviewed above (Brady et al. 2000; Davidson et al. 2001b), sertraline failed to differentiate from placebo in men. Some research suggests that treatment efficacy may vary by gender and by type of traumas experienced. Other research has shown no significant gender differences in sertraline's efficacy in patients with combat-related PTSD (Friedman et al. 2007). Reasons for the sex differences in efficacy findings are not clear, although one possible explanation is that women are more likely than men to

experience sexual or physical trauma and childhood abuse. It is possible that the nature of the trauma itself (age at exposure, chronicity, contextual factors) may alter the biology of the disorder and its responsiveness to medication ([Stein et al. 2006](#)). Some data suggest that certain serotonin transporter genotypes may be associated with better outcomes ([Mushtaq et al. 2012](#)).

Findings from a U.S. Department of Veterans Affairs (VA) medical center study failed to demonstrate that sertraline was superior to placebo in patients with predominantly combat-related PTSD ([Friedman et al. 2007](#)), but a subsequent trial in Iranian combat veterans ( $n=70$ ) did show robust efficacy for sertraline compared with placebo ([Panahi et al. 2011](#)).

Sertraline long-term benefit for PTSD was demonstrated in a prospective study in which patients with PTSD who had completed 12 weeks of double-blind, placebo-controlled acute-phase treatment with sertraline ([Brady et al. 2000](#)) were enrolled in a 24-week open-label continuation phase ([Londborg et al. 2001](#)). It was observed that about 20%–25% of the total improvement in PTSD symptoms occurred during the continuation phase (weeks 12–36). The greatest improvement over time was among patients who were originally considered “nonresponders” in the acute phase, leading the authors to conclude that as many as one-third of PTSD patients may require longer treatment to achieve a clinically significant response. Sertraline’s efficacy in sustaining improvement and preventing PTSD relapse was also examined in a 28-week double-blind continuation study ( $n=96$ ) ([Davidson et al. 2001a](#)). Sertraline was found to be superior to placebo on the three primary outcome measures: full syndrome relapse (sertraline vs. placebo, 5.3% and 26.1%, respectively), relapse or discontinuation

due to clinical deterioration (sertraline vs. placebo, 15.8% and 45.7%, respectively), and acute exacerbation (sertraline vs. placebo, 15.8% and 52.2%, respectively). The relative risk of relapse (RR) after discontinuing sertraline was 6.35.

## Off-Label Use and Special Populations

Sertraline has also been studied for off-label use in the treatment of a variety of disorders.

### **Mood Symptoms in Neurological Conditions**

Sertraline has been used to treat mood symptoms associated with a number of neurological conditions, including depression associated with Parkinson's disease ([Antonini et al. 2006](#); [Hauser and Zesiewicz 1997](#); [Meara and Hobson 1998](#)) and depression-linked fatigue in multiple sclerosis ([Mohr et al. 2003](#)). A study in children and adolescents with epilepsy and depression demonstrated sertraline's efficacy in treating depressive symptoms while maintaining good seizure control ([Thomé-Souza et al. 2007](#)). A 10-week study of sertraline in patients with chronic tension headaches showed a decline in analgesic medication use, suggesting that sertraline may be a good alternative for patients who cannot tolerate the adverse events associated with TCAs ([Singh and Misra 2002](#)). Sertraline also has been used to improve pathological crying and pseudobulbar-type affects ([Benedek and Peterson 1995](#); [Mukand et al. 1996](#); [Okun et al. 2001](#); [Peterson et al. 1996](#)).

## Depression and Cognitive Dysfunction in Elderly Patients With and Without Dementia

Following initial results suggesting a possible role for sertraline in Alzheimer's disease ([Lyketsos et al. 2000](#); [Magai et al. 2000](#)), subsequent studies failed to demonstrate the drug's superiority to placebo at 12, 13, and 24 weeks ([Banerjee et al. 2011](#); [Rosenberg et al. 2010](#); [Weintraub et al. 2010](#)). A recent small study comparing sertraline, venlafaxine, and desipramine in depressed patients with Alzheimer's disease reported significant improvement over baseline in cognitive test performance for all three drugs, with the most widespread effects noted for sertraline ([Mokhber et al. 2014](#)). Sertraline additionally appears to improve subsyndromal depressive symptoms and cognitive function in elderly patients without dementia ([Rocca et al. 2005](#)).

## Substance Use Disorders

Numerous studies have examined the potential for sertraline to benefit patients with substance use disorders. An acute-phase trial of sertraline in DSM-IV alcohol dependence did not indicate its benefit over placebo ([Kranzler et al. 2006](#)), but subsequent analyses and follow-up data suggested potential benefit for alcohol-dependent patients with certain genotypes ([Kranzler et al. 2012](#)). The combination of sertraline plus naltrexone may be particularly useful for treating depressive symptoms and maintaining sobriety in individuals with co-occurring depression and alcohol dependence ([Pettinati et al. 2010](#)). Most studies of sertraline for dependence on other substances of abuse—such as methamphetamine ([Shoptaw et al. 2006](#)), opiates ([Carpenter et al. 2004](#)), or cocaine

([Winhusen et al. 2005](#))—do not suggest any benefit from sertraline in helping to curb substance use. However, a recent trial did find that in comparison with placebo, sertraline delayed the time to relapse in cocaine-dependent patients with depressive symptoms ([Oliveto et al. 2012](#)).

## **Depression in Cardiovascular Disease**

Sertraline is one of the few antidepressants shown to be safe for the treatment of depression in patients with cardiovascular disease. In a well-publicized study by the Sertraline Antidepressant Heart Attack Randomized Trial (SADHART) Group, 369 patients with a recent myocardial infarction or hospitalization for unstable angina who also met criteria for a current major depressive episode were randomly assigned to receive sertraline (at flexible dosages of 50–200 mg/day) or placebo for 24 weeks ([Glassman et al. 2002](#)). There were no significant treatment-emergent effects of sertraline on cardiac measures (including change from baseline left ventricular ejection fraction [LVEF], runs of ventricular premature complexes, or prolonged QTc intervals). For the entire sample, sertraline was superior to placebo in improving rates of response when defined by CGI ratings, but not when defined by Ham-D scores ([Glassman et al. 2002](#)). A separate analysis of the SADHART data showed a trend for sertraline-treated patients to have fewer psychiatric or cardiovascular hospitalizations during the treatment period ([O'Connor et al. 2005](#)) and indicated that sertraline was most beneficial for those patients whose depressive episodes predated the acute cardiac syndrome, those who had a past history of MDD, and those whose episodes were of greater severity ([Glassman et al. 2006](#)). However, although sertraline's safety was again demonstrated in a study of 469 SADHART patients with

chronic heart failure (CHF), in this sample there was no evidence of antidepressant superiority of sertraline over placebo ([O'Connor et al. 2010](#)). Compared with nonremitting patients, CHF patients who achieved remission from depression had fewer cardiovascular events at pretreatment baseline and went on to have better cardiovascular outcomes over a 5-year period ([Jiang et al. 2011](#)).

Sertraline alone and sertraline in combination with coping skills training showed efficacy in treating noncardiac chest pain, including associated symptoms of catastrophizing and anxiety ([Keefe et al. 2011](#)).

Other data relevant to cardiac health include a sertraline trial in nondepressed patients with chronic ischemic heart failure, in which the drug appeared to decrease ventricular extrasystoles ([Leftheriotis et al. 2010](#)). Although the potential mechanism of its cardiovascular benefit is not entirely clear, sertraline may decrease platelet adherence, thereby reducing the likelihood of recurrent myocardial events ([McFarlane et al. 2001](#); [Shapiro et al. 1999](#)).

A review of the literature relevant to abnormal bleeding associated with sertraline and other SSRIs suggested increased risk for gastrointestinal bleeding may be caused by an SSRI-induced increase in gastric acid secretion, whereas a protective effect against ischemic heart disease may be attributable to SSRI effects on platelet reactivity, endothelial reactivity, and inflammatory markers ([Andrade et al. 2010](#)). Of note, examination of pretreatment inflammatory markers in a sample ( $n=122$ ) with coronary heart disease (CHD) and comorbid depression did not suggest that elevated baseline inflammatory markers predicted inferior response to sertraline ([Bot et al. 2011](#)), but depressed CHD patients with comorbid obstructive

sleep apnea/hypopnea syndrome had inferior outcomes with sertraline ([Roest et al. 2012](#)). Other studies have demonstrated that sertraline can improve quality of life in depressed patients with acute coronary syndrome ([Swenson et al. 2003](#)) or a recent stroke ([Murray et al. 2005](#)).

A meta-analysis of 16 studies involving about 4,300 patients reported that TCAs and citalopram were associated with significantly greater QTc prolongation than were sertraline, paroxetine, or fluvoxamine ([Beach et al. 2014](#)).

## **Depression in Cancer**

Sertraline has been studied in patients with cancer and depression. A 12-week open-label, flexible-dose trial of sertraline in patients undergoing chemotherapy demonstrated positive effects on depressed mood ([Torta et al. 2008](#)), but in a controlled trial of almost 200 patients with advanced disease who did not have MDD, sertraline had no mood benefit over placebo ([Stockler et al. 2007](#)).

## **Vasomotor Symptoms**

Another proposed off-label use for sertraline is the alleviation of hot flashes associated with menopause ([Aedo et al. 2011](#); [Gordon et al. 2006](#); [Grady et al. 2007](#)) or with tamoxifen treatment for breast cancer ([Kimmick et al. 2006](#)) in women, as well as in men following medical castration for advanced prostate cancer ([Roth and Scher 1998](#)). One study suggested that a positive response to sertraline for hot flashes is related to activity level, education, and menopausal status ([Kerwin et al. 2007](#)).

Sertraline was superior to placebo in a study that examined its potential for controlling hot flashes in women with or at high risk of breast cancer, for whom hormone therapy was not recommended ([Wu et al. 2009](#)).

## Other Uses

There has been some research investigating sertraline's potential benefit in a variety of other conditions.

Sertraline has been used successfully in the treatment of children and adolescents with MDD and dysthymic disorder ([Ambrosini et al. 1999](#); [Nixon et al. 2001](#)), and it has demonstrated some utility in the treatment of depression in patients with schizophrenia ([Addington et al. 2002](#); [Kirli and Caliskan 1998](#); [Mulholland et al. 2003](#)). One study in patients with MDD showed that sertraline increased adaptive traits associated with psychopathic personality (social charm and interpersonal and physical boldness) and reduced maladaptive traits associated with psychopathy (dysregulated impulsivity and externalization), independent of its antidepressant effects ([Dunlop et al. 2011](#)).

Sertraline has also shown some benefit in the treatment of generalized anxiety disorder (GAD). Two randomized GAD trials showed that sertraline had superiority over placebo ([Allgulander et al. 2004](#); [Brawman-Mintzer et al. 2006](#)) and efficacy similar to that of paroxetine ([Ball et al. 2005](#)). In a placebo-controlled trial ([Rynn et al. 2001](#)), sertraline was both effective and safe in children with GAD.

Results from some investigations suggest a role for sertraline in the treatment of various eating disorders, including anorexia nervosa ([Santonastaso et al. 2001](#)), bulimia nervosa ([Milano et al. 2004](#)), binge-eating disorder ([Leombruni et al. 2006](#); [McElroy et al. 2000](#)), and night-eating syndrome ([O'Reardon et al. 2006](#)).

Several studies have reported sertraline's benefit in treating premature ejaculation ([Arafa and Shamloul 2006](#); [Biri et al. 1998](#)).

Trials of sertraline for DSM-IV impulse-control disorders have yielded mixed results; positive outcomes were observed in a trichotillomania sample ([Dougherty et al. 2006](#)), but no therapeutic effect was demonstrated for gambling disorders ([Saiz-Ruiz et al. 2005](#)).

A number of studies have highlighted the effective use of sertraline in treating aggressive and self-harming behaviors ([Buck 1995](#); [Feder 1999](#)), specifically in patients with personality disorders ([Kavoussi et al. 1994](#)), patients with Huntington's disease ([Ranen et al. 1996](#)), and adults with intellectual disability or autism spectrum disorder ([Hellings et al. 1996](#); [McDougle et al. 1998](#)).

Sertraline has proved useful in preventing dialysis-induced hypotension, a condition that can be exacerbated by other antidepressive agents ([Perazella 2001](#)). Sertraline also has been of benefit in treating pruritus associated with cholestatic liver disease ([Mayo et al. 2007](#)). Finally, it has been shown to reduce symptom severity in refractory tinnitus ([Zöger et al. 2006](#)).

## Side Effects and Toxicology

---

Sertraline has been demonstrated to have a low incidence of anticholinergic, sedative, and cardiovascular effects because of its low affinity for adrenergic, cholinergic, histaminergic, and benzodiazepine receptors. However, in premarketing evaluations, sertraline was associated with a number of adverse effects. The most commonly reported

side effects were gastrointestinal disturbance (nausea, 27%; diarrhea/loose stools, 21%), sleep disturbance (insomnia, 22%; somnolence, 14%), headache (26%), dry mouth (15%), and sexual dysfunction (ejaculation failure, 14%; decreased libido, 6%). Other side effects reported by subjects and described as frequent (i.e., occurring in at least 1 of 100 subjects) in premarketing pooled data from clinical trials included impotence, palpitations, chest pain, hypertonia, hypoesthesia, increased appetite, back pain, asthenia, malaise, weight gain, myalgia, yawning, rhinitis, and tinnitus ([Pfizer 2016](#)).

## Hyponatremia

Sertraline and other SSRIs have been associated with cases of hyponatremia, as well as with the syndrome of inappropriate antidiuretic hormone (SIADH) secretion (see [Bouman et al. 1997](#); [Bradley et al. 1996](#); [Catalano et al. 1996](#); [Goldstein et al. 1996](#); [Kessler and Samuels 1996](#)). [Bradley et al. \(1996\)](#), in a review of the literature, noted that the average age of patients experiencing SIADH was greater than 70 years, suggesting that the elderly may be more vulnerable to age-related changes in water balance, which may make them more susceptible to developing SIADH with an SSRI.

## Extrapyramidal Side Effects

Extrapyramidal side effects (EPS), including dyskinesias, dystonias, and akathisia, have been observed with sertraline use, although they are infrequent ([Altshuler and Szuba 1994](#); [Lambert et al. 1998](#); [Madhusoodanan and](#)

[Brenner 1997](#); [Opler 1994](#)). [Hamilton and Opler \(1992\)](#) suggested that the underlying mechanism of SSRI-induced akathisia is serotonergic inhibition of the nigrostriatal dopamine pathway, which can be associated with parkinsonism ([Leo et al. 1995](#); [Pina Latorre et al. 2001](#)). [Madhusoodanan and Brenner \(1997\)](#), in a case report of choreiform dyskinesia and EPS associated with sertraline therapy, proposed that 5-HT-driven antagonism of dopaminergic transmission in the nigrostriatal pathway, as well as in the ventral tegmental area, might be responsible.

## Sexual Dysfunction

Sexual dysfunction is a well-known side effect of SSRIs, including sertraline. A Cochrane Database review noted that although limited evidence is available, some trials have suggested that the addition of sildenafil or bupropion can reduce antidepressant-induced erectile dysfunction in men ([Rudkin et al. 2004](#)).

## Rare Adverse Events

Other adverse events associated with sertraline are rare and include seizures ([Raju et al. 2000](#); [Saraf and Schrader 1999](#)), stuttering ([Brewerton et al. 1996](#); [Christensen et al. 1996](#); [McCall 1994](#)), altered platelet function and bleeding time ([Calhoun and Calhoun 1996](#); [Mendelson 2001](#)), and galactorrhea ([Bronzo and Stahl 1993](#); [Lesaca 1996](#)). Urinary hesitancy and retention have been reported in a few cases in women ([Lowenstein et al. 2007](#)). A study in GAD reported significantly greater bone density loss in

patients who received 12 months of sertraline treatment versus those treated with other SSRIs ([Ak et al. 2015](#)).

## Increased Risk of Suicidality

In common with all other antidepressants, sertraline carries an FDA black box warning regarding an increased risk of suicidality in children and adolescents, although there are no specific data indicating increased rates of suicide in children treated with sertraline. One specific study of suicidal thinking and behavior in more than 700 older adults with late-life depression showed no increase in suicidality with sertraline treatment versus placebo ([Nelson et al. 2007](#)).

## Discontinuation Syndrome

Sertraline has been associated with a discontinuation syndrome. [Leiter et al. \(1995\)](#) described two cases in which patients experienced alterations in mood, cognition, energy, gait, and equilibrium, in addition to gastrointestinal symptoms, headaches, and paresthesias. Elsewhere there have been reports of insomnia, impaired short-term memory, myalgias, dyspnea, and chills without fevers ([Louie et al. 1994](#)). In a systematic 28-week study in patients with panic disorder ([Rapaport et al. 2001](#)), abrupt discontinuation of sertraline was primarily associated only with insomnia (15.7% of patients randomly assigned to placebo vs. 4.3% continuing on sertraline) and dizziness (4.3% of patients continuing to take sertraline and 16.4% switched to placebo). There was no statistically significant

increase in headache or in general malaise in patients randomly assigned to switch to placebo.

## Use During Pregnancy and Lactation

The safety of sertraline and other SSRIs during pregnancy is discussed in [Chapter 57](#) of this volume (“Psychopharmacology During Pregnancy and Lactation,” by Ray-Griffith, Newport, and Stowe). A recent large-scale study in Quebec reported that exposure to sertraline during the first trimester was associated with an increased risk of cardiac (atrial/ventricular) effects and craniosyntosis ([Bérard et al. 2015](#)). In contrast, a recent major review of SSRIs in breast feeding concluded that sertraline and paroxetine are the preferred agents (in regard to the infant’s health) for nursing women who require antidepressant treatment ([Orsolini and Bellantuono 2015](#)).

---

## Drug-Drug Interactions

---

Sertraline has a number of potential drug-drug interactions. Because the drug is tightly bound to plasma proteins, caution should be employed when sertraline is used in combination with pharmaceuticals possessing similar characteristics, such as warfarin, and prothrombin time should be monitored when sertraline and warfarin are used concurrently ([Pfizer 2016](#)). The potential for serotonin syndrome may be increased when sertraline is used in combination with other SSRIs, serotonin-norepinephrine reuptake inhibitors, or triptans prescribed for the acute treatment of migraines. Coadministration of sertraline with

an MAOI is contraindicated because of the significant risk of serotonin syndrome with this combination.

The degree of sertraline's inhibition of the CYP system, most significantly CYP2D6, is relatively minor in comparison with that of other SSRIs, such as fluoxetine and paroxetine ([Preskorn et al. 2007](#)), although mouse data have shown a mild pharmacokinetic drug-drug interaction between bupropion and sertraline that leads to a small elevation in bupropion metabolism ([Molnari et al. 2012](#)). Because TCAs are substrates of CYP2D6, drug levels and dosages need to be closely monitored when TCAs are used in combination with sertraline.

Sertraline, in common with its fellow SSRIs citalopram and escitalopram, is also metabolized by the CYP2C19 isoenzyme, which is inhibited by proton pump inhibitors (PPIs). In a study examining the effect of PPIs on serum concentrations of SSRIs, coadministration of the PPI esomeprazole led to significant elevations (+38.5%;  $P=0.0014$ ) in sertraline blood levels but caused an almost twofold increase (+81.8%;  $P<0.001$ ) in escitalopram blood levels ([Gjestad et al. 2015](#)).

---

## Conclusion

---

Controlled clinical trials support sertraline's efficacy in the treatment of a variety of psychiatric conditions, including depressive and anxiety disorders, and uncontrolled studies suggest an expanded role for sertraline in a number of other conditions. Sertraline's safety profile is superior to that of older antidepressant agents, thus increasing the

potential target population of patients in whom sertraline treatment can be beneficial.

# CHAPTER 12

## Paroxetine

**Paroxetine** (marketed as Paxil, Pexeva, and Brisdelle) is classified as one of the selective serotonin reuptake inhibitors (SSRIs) because of its potent inhibition of presynaptic serotonin (5-hydroxytryptamine [5-HT]) uptake. It is also a relatively potent norepinephrine reuptake inhibitor, particularly at higher dosages. Paroxetine has received U.S. Food and Drug Administration (FDA) approval for the treatment of depression, panic disorder, social anxiety disorder (social phobia), generalized anxiety disorder, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), premenstrual dysphoric disorder (PMDD), and vasomotor symptoms (hot flashes) associated with menopause (the latter in a low-dosage formulation marketed as Brisdelle). Paroxetine also

has demonstrated efficacy in child and adolescent OCD and social anxiety disorder.

Paroxetine is available in 10-, 20-, 30-, and 40-mg tablets and in suspension form. A controlled-release (CR) formulation, available in 12.5-, 25-, and 37.5-mg tablets, exhibits equal or better efficacy than the paroxetine immediate-release (IR) formulation, as well as clear advantages in tolerability ([Golden et al. 2002](#)). Paroxetine is also available in 7.5-mg capsules in the Brisdelle formulation, approved for vasomotor symptoms associated with menopause.

---

## History and Discovery

---

The synthesis of the first SSRI, fluoxetine, in 1972 marked the inception of an exciting new era of scientific and clinical innovation in psychiatry ([Wong et al. 1995](#)). Prior to this discovery, psychiatrists had only a few classes of pharmacological treatments for managing depression and anxiety. These medication classes, including tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), and benzodiazepines, were indeed efficacious; however, they were poorly tolerated and therefore quite limited in usefulness.

Shortly after the introduction of fluoxetine into the U.S. market in 1988, a marked increase in research led to the development of other SSRIs, which ultimately proved effective in a wide array of psychiatric disorders. In 1992, paroxetine became the third SSRI to be approved by the FDA for the treatment of depression. Since then, the FDA has also approved it for the treatment of panic disorder,

social anxiety disorder, generalized anxiety disorder, OCD, PTSD, PMDD, and hot flashes associated with menopause.

---

## Structure-Activity Relations and Pharmacological Profile

---

Paroxetine ([Figure 12-1](#)) is the most potent inhibitor of the serotonin transporter (5-HTT) among the SSRIs ([Frazer 2001](#)); 85%–100% of 5-HTT binding sites are occupied following 20- to 40-mg daily dosages of paroxetine ([Kent et al. 2002](#); [Meyer et al. 2001](#)), and transporter binding is maintained for up to 14 days after 4 weeks of treatment ([Magnussen et al. 1982](#); [Thomas et al. 1987](#)).

---

**FIGURE 12-1.** Chemical structure of paroxetine.

Paroxetine is also the most potent inhibitor of the norepinephrine transporter (NET) among drugs classified as SSRIs, although paroxetine's NET antagonism does not

approach the magnitude of its 5-HTT antagonism ([Finley 1994](#)). In an 8-week high-dosage forced-titration protocol comparing paroxetine CR dosages of 12.5 mg/day and 75 mg/day with venlafaxine extended release (XR) dosages of 75–375 mg/day, both paroxetine and venlafaxine produced dose-dependent inhibition of the 5-HTT and the NET ([Owens et al. 2008](#)); at 8 weeks, maximal 5-HTT inhibition for paroxetine and venlafaxine was 90% and 85%, respectively, and maximal NET inhibition was 33% and 61%. Substantial NET antagonism occurs at paroxetine IR dosages of 40 mg/day and higher ([Gilmor et al. 2002](#)).

Paroxetine has no appreciable affinity for the dopamine transporter (DAT) or for dopamine type 1 ( $D_1$ ), dopamine type 2 ( $D_2$ ), serotonin type 1A ( $5-HT_{1A}$ ), serotonin type 2A ( $5-HT_{2A}$ ),  $\alpha_1$ - and  $\alpha_2$ -adrenergic, and histamine type 1 ( $H_1$ ) receptors ([Hyttel 1994](#); [Owens et al. 1997](#)). It is distinguished from sertraline by its high affinity for the NET and low affinity for the DAT. Sertraline, by contrast, has a relatively high affinity for the DAT but no affinity for the NET ([Tulloch and Johnson 1992](#)). The affinity of paroxetine for the muscarinic cholinergic receptor is similar to that of desipramine, although paroxetine is used at lower dosages than desipramine and is therefore less anticholinergic than this tricyclic agent. However, this property may account for paroxetine's mild anticholinergic side effects, including dry mouth, blurry vision, and constipation ([Owens et al. 1997](#)).

---

## Pharmacokinetics and Disposition

---

Paroxetine is well absorbed from the alimentary tract, and absorption is not affected by the presence or absence of food ([Kaye et al. 1989](#)). Paroxetine is highly lipophilic and is readily distributed into peripheral tissues, with a high volume of distribution and 95% protein binding ([Kaye et al. 1989](#)). Oral bioavailability is affected by extensive first-pass metabolism ([Lane 1996](#)). With serial dosing, bioavailability increases as the hepatic metabolic system becomes saturated and a larger proportion of the parent compound enters systemic circulation ([Kaye et al. 1989](#)). Following oral dosing, steady-state concentrations of paroxetine exhibit wide intersubject variability ([Sindrup et al. 1992a](#)); however, there appears to be no relationship between paroxetine levels and clinical response or adverse outcomes ([Tasker et al. 1989](#)).

The rate-limiting step in the metabolism of paroxetine is the cytochrome P450 (CYP) 2D6 enzyme system ([Crewe et al. 1992](#); [Sindrup et al. 1992a](#)). Genetic studies have demonstrated up to 40 polymorphisms of the 2D6 enzyme, which in part may explain the differences in pharmacokinetic parameters observed among individuals ([Lane 1996](#)). Individuals can be categorized by CYP2D6 phenotype as being poor, intermediate, extensive, or ultrarapid metabolizers, denoting that they have very high, high, low, or very low serum paroxetine concentrations, respectively ([Charlier et al. 2003](#)). Ultrarapid metabolizers may be at greater risk of antidepressant nonresponse, although this has not been clearly demonstrated, and paroxetine's minimum therapeutic concentration is not well defined. Similarly, a putative increased risk of adverse events for poor metabolizers has not been confirmed ([Hicks et al. 2015](#)). Patients with negligible or diminished CYP2D6

activity are thought to use alternative enzyme systems (Gunasekara et al. 1998; Lane 1996).

Paroxetine is the most potent inhibitor of the CYP2D6 enzyme system among the SSRIs (Crewe et al. 1992; Nemeroff et al. 1996), and its inhibition of 2D6 can continue for up to 5 days after discontinuation (Liston et al. 2002). As both a substrate and an inhibitor of its own metabolism, paroxetine has a nonlinear pharmacokinetic profile, such that higher dosages produce disproportionately greater plasma drug concentrations as the enzyme becomes saturated (Preskorn 1993). With paroxetine IR, peak plasma concentration is attained in approximately 5 hours, and plasma steady-state concentration is achieved within 4–14 days (Kaye et al. 1989). The terminal half-life ( $t_{1/2}$ ) of the parent compound is approximately 1 day and increases at higher dosages, consequent to autoinhibition of CYP2D6 (Preskorn 1993). The pharmacokinetic properties of paroxetine appear to be affected by age. Bayer et al. (1989) reported a threefold increase in maximum plasma concentration in elderly subjects compared with younger subjects following a single dose of paroxetine. Furthermore, the  $t_{1/2}$  in the elderly subgroup was extended by nearly 100%.

In individuals with renal impairment, both half-life and maximum plasma levels of paroxetine have been shown to increase relative to the extent of renal disease (Doyle et al. 1989). In patients with severe liver disease, there are considerable elevations in the steady-state concentration and the  $t_{1/2}$  of paroxetine (Dalhoff et al. 1991). Patients with substantial renal or hepatic impairment should initially receive lower paroxetine dosages to avoid potential side effects.

Paroxetine CR is designed to slow absorption and delay the release of paroxetine until after the tablet has passed through the stomach. With this formulation, 20% of the drug is excreted unchanged from the gastrointestinal tract, such that 20% higher dosages of paroxetine CR are necessary to achieve the same bioavailability ([DeVane 2003](#)). Dissolution after single dosing takes 4–5 hours; otherwise paroxetine CR displays the same pharmacokinetic parameters as the IR formulation with regard to  $t_{1/2}$  and nonlinearity.

Paroxetine mesylate is a generic formulation. Although no studies have compared this formulation's efficacy against that of paroxetine hydrochloride and its bioequivalence has not been precisely established, case reports have indicated problems of decreased efficacy and poor tolerability in patients switched from paroxetine hydrochloride to paroxetine mesylate ([Borgheini 2003](#)).

---

## Pharmacogenomics

---

Paroxetine's primary mode of action is likely mediated by its binding to the 5-HTT. A well-known polymorphism (5-HT transporter gene-linked polymorphic region [5-HTTLPR]) has been located in the promoter region of the gene (*SLC6A4*) that encodes 5-HTT. This polymorphism may be a pharmacogenetic marker for antidepressant efficacy. The 5-HTTLPR polymorphism was first reported as two alleles, referred to as *long* (L) and *short* (S); a third allele (Lg) has also been identified but has not been studied in relation to SSRI response to any great extent. There exists some evidence that cells with the S allele express 50% less 5-HTT

than cells with the L allele, resulting in reduced efficacy of SSRI medications, including paroxetine (Lotrich et al. 2008; Zanardi et al. 2000). The S allele may influence tolerability of paroxetine as well (Murphy et al. 2004). Because patients with the S allele have less expression of 5-HTT, they require a higher serum paroxetine concentration to achieve an effect (Lotrich et al. 2008). It may be that patients with major depressive disorder who are L/L homozygotes have greater 5-HTT occupancy and improved clinical response (Ruhé et al. 2009b). However, the association of the L allele with improved clinical response to paroxetine has not been consistently observed (Kato et al. 2015; Seripa et al. 2015), and a meta-analysis found that this polymorphism does not usefully predict clinical response to SSRIs (Taylor et al. 2010).

Another possible genetic marker for antidepressant efficacy is the T102C single nucleotide polymorphism (rs6313) in the 5-HT<sub>2A</sub> gene (*5HTR2A*). Survival analysis has shown a more or less linear relationship between the number of C alleles and the odds of patients discontinuing paroxetine therapy because of untoward effects (Murphy et al. 2003).

Evidence that antidepressants exert their effects through brain-derived neurotrophic factor (BDNF) led to the hypothesis that polymorphisms in the *BDNF* gene may be associated with antidepressant response. However, studies testing this link have yielded mixed results (Notaras et al. 2015).

Another possible influence on antidepressant efficacy is the concentration of medication that reaches the brain. Evidence indicates that paroxetine, among other antidepressants such as sertraline, citalopram, amitriptyline, and venlafaxine, is actively transported across

the blood-brain barrier and out of the brain by the P-glycoprotein (P-gp) transporter ([Uhr et al. 2008](#)). P-gp is encoded by the adenosine triphosphate (ATP)-binding cassette, subfamily B, member 1 transporter (*ABCB1*) gene, also known as multidrug-resistance gene 1 (*MDR1*). Variable activity of P-gp may help explain why serum concentrations of SSRIs are poor predictors of efficacy ([Mitchell 2004](#)). A number of studies now indicate that polymorphisms of *ABCB1* may influence the efficacy of paroxetine ([Gex-Fabry et al. 2008](#); [Kato et al. 2008](#); [Ray et al. 2015](#); [Sarginson et al. 2010](#); [Uhr et al. 2008](#)).

In addition to the candidate gene studies mentioned here, several genomewide association studies have been conducted but have not identified any polymorphisms likely to exert a strong influence on SSRI response ([Biernacka et al. 2015](#)).

---

## Mechanism of Action

---

Paroxetine and all of the other SSRIs cause immediate elevations in extracellular 5-HT concentrations in serotonergic synapses, resulting from the decreased 5-HT clearance associated with 5-HTT inhibition ([Wagstaff et al. 2002](#)). Paroxetine initially causes a paradoxical *decrease* in 5-HT neurotransmission, likely due to activation of a negative feedback system mediated by increased 5-HT binding to the 5-HT<sub>1A</sub> autoreceptor and subsequent diminution in serotonergic neural activity ([Blier et al. 1990](#)). After 2 weeks of paroxetine treatment, the 5-HT<sub>1A</sub> autoreceptors are desensitized, and there is an associated increase in serotonergic neurotransmission ([Chaput et al.](#)

1991). The delayed changes in 5-HT<sub>1A</sub> receptor sensitivity and 5-HT neurotransmission seen after long-term daily paroxetine use are temporally associated with clinical improvement, hinting at a possible mechanistic link.

Pindolol, a nonselective  $\beta$ -adrenergic receptor antagonist/5-HT<sub>1A</sub> receptor antagonist, has been studied as a novel approach to accelerate the therapeutic response to SSRIs, as well as to convert SSRI nonresponders to responders. It was hypothesized that blockade of the presynaptic 5-HT<sub>1A</sub> autoreceptor might prevent the initial reduction in serotonergic transmission that occurs with SSRIs, leading to a more rapid and robust clinical response (Pérez et al. 1999).

This hypothesis was supported by results from open studies and from several double-blind, placebo-controlled trials indicating that the addition of pindolol (2.5–5.0 mg three times a day) to paroxetine in the early phase of treatment for major depressive disorder increased the rapidity of clinical improvement (Artigas et al. 1994; Blier and Bergeron 1995). However, data on augmentation of clinical efficacy with pindolol were not compelling, especially in individuals with depression refractory to paroxetine monotherapy (Bordet et al. 1998; Pérez et al. 1999; Tome et al. 1997; Zanardi et al. 1997). In another study, paroxetine with pindolol augmentation was found to be most efficacious in patients with depression who were drug naive and in patients with bipolar depression (Geretsegger et al. 2008). It may be that the dosages of pindolol previously studied were inadequate to obtain a response (Martinez et al. 2000).

Paroxetine has also been shown to have an effect on the hypothalamic-pituitary-adrenal (HPA) axis. It is well

established that many individuals with depression have HPA axis hyperactivity and hypersecretion of corticotropin-releasing factor (CRF) from the hypothalamic and extrahypothalamic circuits ([Heim and Nemeroff 1999](#)). Early life stress is associated with hyperactivity of the HPA axis and increased CRF messenger RNA (mRNA) expression ([Nemeroff 1996](#); [Newport et al. 2002](#)). In adult animals, these effects are reversed by chronic—but not acute—paroxetine treatment.

---

## Indications and Efficacy

---

### Major Depressive Disorder

#### Comparisons With Other Agents

The efficacy of paroxetine in major depressive disorder has been established in several randomized, placebo-controlled studies, as well as in studies comparing the effects of paroxetine with those of other antidepressants, including TCAs, serotonin-norepinephrine reuptake inhibitors (SNRIs), and other SSRIs. Many studies have compared paroxetine with other SSRIs; however, many of these studies were sponsored by the pharmaceutical industry and therefore must be evaluated with caution. The earliest placebo-controlled trials used paroxetine dosages of 10–50 mg/day and were 6 weeks in duration. Outcome variables used were typically the Hamilton Rating Scale for Depression (Ham-D), the Montgomery-Åsberg Depression Rating Scale (MADRS), and the Clinical Global Impressions (CGI) Scale to assess improvement. A recent meta-analysis

of all published and unpublished industry-sponsored trials that included Ham-D change scores showed superiority of paroxetine over placebo, with a modest effect size of  $d=0.32$  ([Sugarman et al. 2014](#)).

There has been some debate regarding the use of such scales in the assessment of medication efficacy, as well as concerns that there exists a publication bias toward positive results. A minority of authors have suggested that “hard measures” of treatment effectiveness—namely, suicide attempts, treatment switching, hospital admission, job loss, or dropout from the trial ([Barbui et al. 2008](#))—be used instead, although such endpoints are not currently acceptable to the FDA. [Barbui et al. \(2008\)](#) undertook a systematic review of paroxetine, evaluating both published and unpublished data according to one specific hard measure—treatment discontinuation—by looking at the number of patients who left a study early for any reason. The authors found that when this measure was used as a primary outcome, paroxetine was not effective, whereas when rate of response (defined as  $\geq 50\%$  reduction in Ham-D score) was used, paroxetine was superior to placebo ([Barbui et al. 2008](#)).

**Tricyclic and tetracyclic antidepressants.** A meta-analysis by [Montgomery \(2001\)](#) compared the efficacy and tolerability of paroxetine with those of TCAs, including amitriptyline, imipramine, clomipramine, doxepin, and nortriptyline, as well as the tetracyclics mianserin and maprotiline. The data demonstrated no overall significant difference in antidepressant response rates between paroxetine and TCAs or tetracyclics. Paroxetine was better tolerated, had lower rates of discontinuation attributed to

adverse events, and had a greater effect on concomitant anxiety.

**Other SSRIs.** Many studies have found paroxetine and fluoxetine to be equally effective in the treatment of major depressive disorder and associated anxiety ([Chouinard et al. 1999](#); [De Wilde et al. 1993](#); [Fava et al. 1998, 2000](#); [Tignol 1993](#)). Similar results have been obtained from trials comparing paroxetine with sertraline or escitalopram. Equivalent efficacy has been demonstrated in comparisons of paroxetine against either sertraline or escitalopram; however, these studies tend to also show a greater dropout rate in paroxetine groups, likely due to adverse medication effects ([Aberg-Wistedt et al. 2000](#); [Baldwin et al. 2006](#); [Zanardi et al. 1996](#)). Some studies have suggested efficacy differences among the SSRIs, with a Cochrane review concluding that citalopram may be superior to paroxetine in the acute phase of treatment (6–12 weeks) ([Purgato et al. 2014](#)).

**Other agents.** Paroxetine has also been compared with a variety of other agents in the treatment of depression. Nefazodone and paroxetine were shown to possess similar efficacy and tolerability ([Baldwin et al. 1996](#)), and mirtazapine and paroxetine were found to be equivalent in terms of efficacy and tolerability ([Benkert et al. 2000](#)). However, a Cochrane review concluded that mirtazapine may be superior to paroxetine, whereas paroxetine may be superior to the norepinephrine reuptake inhibitor reboxetine in terms of early response to treatment (1–4 weeks) ([Purgato et al. 2014](#)). A post hoc analysis of a clinical trial determined that paroxetine CR was superior to bupropion extended release (XL) in reducing a “psychic

depression” symptom cluster that was correlated with suicidal ideation ([Grunebaum et al. 2013](#)).

In a meta-analysis of the venlafaxine worldwide database, the SNRI venlafaxine showed a slight statistically significant advantage in efficacy over SSRIs as a class, although no such advantage was demonstrated for venlafaxine over paroxetine ([Nemeroff et al. 2003](#)). A study comparing venlafaxine XR and paroxetine in the maintenance treatment of depression found higher rates of remission with venlafaxine ([Shelton et al. 2005](#)). In patients with treatment-resistant depression (defined as inadequate response to appropriate courses of at least two different antidepressants), venlafaxine (200–300 mg/day) was shown to be superior to paroxetine (30–40 mg/day) in bringing about remission ([Poirier and Boyer 1999](#)).

In contrast, a study in Chinese patients with treatment-resistant depression showed no significant differences among paroxetine, mirtazapine, and venlafaxine XR ([Fang et al. 2010](#)). A study comparing paroxetine with the SNRI duloxetine (40–80 mg/day) suggested a higher probability of remission with duloxetine 80 mg/day than with paroxetine ([Goldstein et al. 2004](#)). Another study in Chinese patients found a nonsignificantly higher remission rate with paroxetine compared with duloxetine 40–60 mg/day ([Wang et al. 2015](#)). A study comparing paroxetine with the SNRI milnacipran in Japanese patients showed no difference in efficacy ([Kamijima et al. 2013](#)). In evaluating studies comparing paroxetine with SNRI agents, it is important to take into account the dosages used for paroxetine, because paroxetine 20 mg/day is too low to exhibit any NET blockade.

Paroxetine has also been compared with investigational agents such as substance P (NK<sub>1</sub>) receptor antagonists. In

the Merck-sponsored NK<sub>1</sub> receptor antagonist trials in major depressive disorder, paroxetine 20 mg/day was superior to both placebo and the novel agent ([Cutler et al. 2000](#)).

## **Depression in the Elderly**

Following successful treatment for depression, elderly patients are more likely than nonelderly patients to experience early relapses ([Zis et al. 1980](#)). SSRIs are currently the treatment of choice in this population because of their demonstrated efficacy and their relative safety over TCAs and MAOIs. Whereas paroxetine, clomipramine, and amitriptyline are equally effective in geriatric patients ([Geretsegger et al. 1995](#); [Guillibert et al. 1989](#); [Hutchinson et al. 1992](#)), paroxetine and fluoxetine have both been shown to elicit improved depression response rates and improved cognitive functioning, and they are equally well tolerated ([Geretsegger et al. 1994](#); [Gunasekara et al. 1998](#); [Schöne and Ludwig 1993](#)). Paroxetine and bupropion sustained release (SR) also were shown to be equally effective in this population and to have low discontinuation rates ([Weihs et al. 2000](#)). Paroxetine CR at a daily dosage of 12.5 mg or 25 mg was found to be well tolerated by elderly patients and superior to placebo; at the higher dosage, patients showed numerically larger decreases in total Ham-D scores, and a greater number of patients achieved remission (Ham-D≤7) ([Rapaport et al. 2009](#)). A recent network meta-analysis determined that there is clear evidence for the effectiveness of paroxetine in depression in older adults, but paroxetine may have a greater risk of dizziness compared with placebo ([Thorlund et al. 2015](#)).

For maintenance treatment in elderly ( $\geq 65$  years old) patients with depression, paroxetine and nortriptyline are similarly effective in preventing relapse ([Bump et al. 2001](#)). In a maintenance study comparing continuation of combined treatment consisting of either interpersonal therapy plus paroxetine or interpersonal therapy plus placebo, patients who continued on paroxetine were significantly less likely to experience a recurrence, whereas therapy alone was not successful in preventing relapse ([Reynolds et al. 2006](#)).

One issue of concern in treating the elderly with paroxetine is the potential risk of anticholinergic side effects, leading to delirium. Fluoxetine has minimal anticholinergic activity, and in a study comparing the effects of fluoxetine and paroxetine in depressed elderly patients without dementia, both medications produced marked improvement in cognitive functioning and mood symptoms and were well tolerated ([Cassano et al. 2002](#)). A meta-analysis concluded that paroxetine was not significantly associated with risk of falls in older adults ([Ruxton et al. 2015](#)).

## **Maintenance Treatment of Depression**

Given that it is now well recognized that unipolar depression is a chronic and recurrent disorder, the prevention of recurrence should be a primary aim. Studies have demonstrated the effectiveness of paroxetine in maintaining remission over an extended period without adverse effects ([Duboff 1993](#)), particularly when compared with placebo ([Montgomery and Dunbar 1993](#)). However, studies comparing paroxetine with escitalopram reported that although both medications produced improvement in measures of depression, escitalopram appeared to be more

efficacious and to have better tolerability ([Baldwin et al. 2006](#); [Boulenger et al. 2006](#); [Kasper et al. 2009](#)). The paroxetine dosages used in the long-term studies were typically the same ones used in the acute studies (20–40 mg/day). Thus, for maintenance therapy for depression, the recommended dosage of paroxetine is the dosage that was effective during acute therapy.

In most patients with an acute major depressive episode, an initial daily dosage of 20 mg is sufficient for the duration of the illness episode, at least when response (defined as  $\geq 50\%$  reduction in symptoms) is used as an endpoint ([Dunner and Dunbar 1992](#)). One study demonstrated that in patients with major depressive disorder, dosage escalation of 20 mg/day and subsequent increased plasma levels were not associated with improved clinical outcomes ([Ruhé et al. 2009a](#)). However, to improve the likelihood of remission, we recommend increasing the dosage in 10-mg increments each week—up to 50 mg/day or more of the IR form and up to 75 mg/day of the CR form ([Nemeroff 1993](#)). For elderly patients and those with renal or hepatic dysfunction, paroxetine should be initiated at a lower dosage, with gradual dosage titration to therapeutic effect while monitoring for side effects.

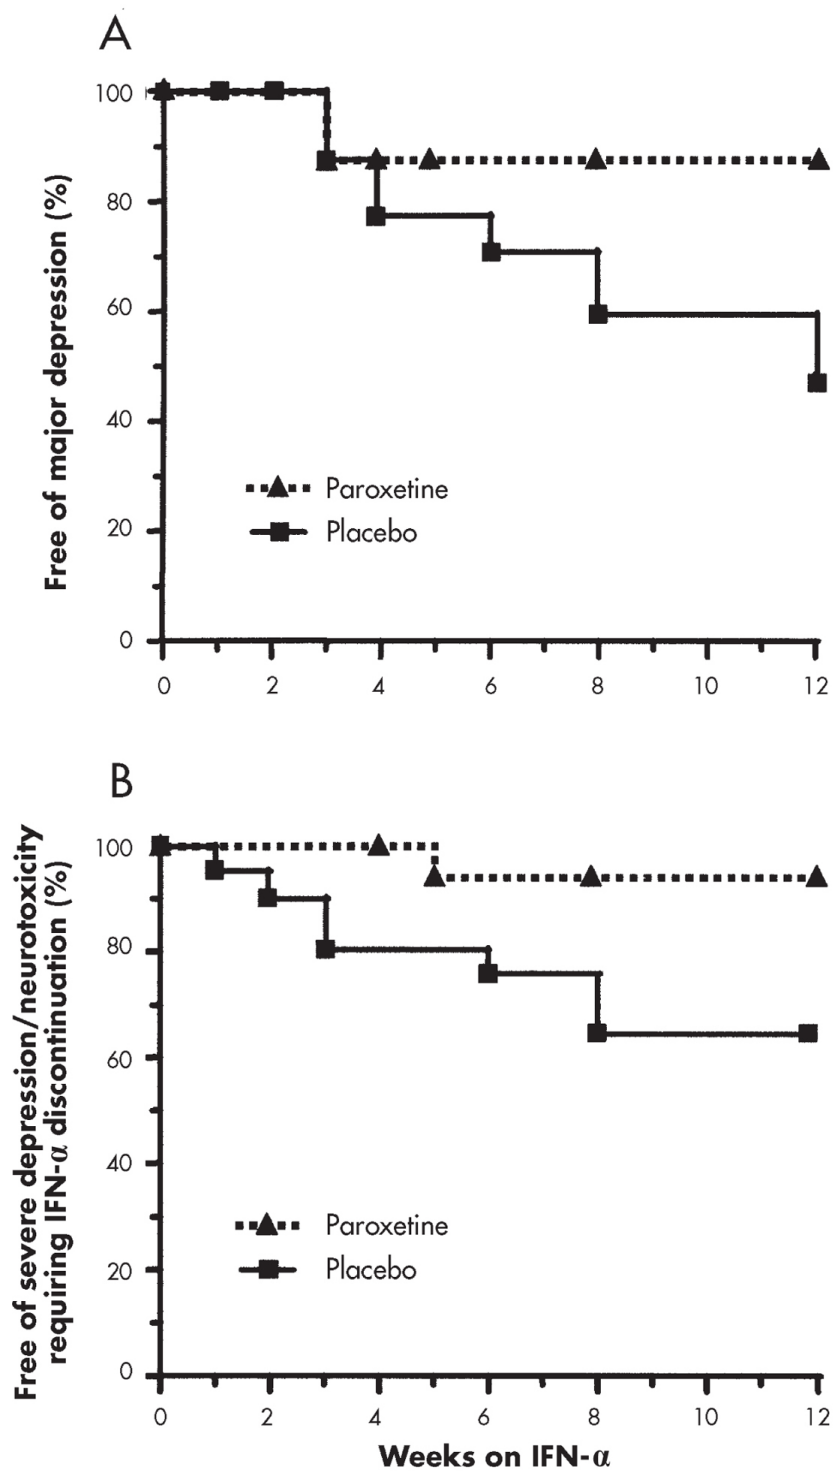

## **Adjunctive Treatment of Bipolar Depression**

Paroxetine has demonstrated efficacy and safety in the adjunctive treatment of bipolar depression, an often treatment-refractory disorder. In one study in lithium-treated patients, augmentation with paroxetine was shown to be superior to augmentation with amitriptyline ([Bauer et al. 1999](#)). In another study, paroxetine and imipramine were not significantly different from placebo in terms of overall efficacy, but both were superior to placebo among

patients with a low serum lithium level ([Nemeroff et al. 2001](#)). Another study evaluating antidepressant augmentation of a mood stabilizer showed no differences in efficacy among paroxetine, bupropion SR, and placebo ([Sachs et al. 2007](#)). Paroxetine was not associated with an increased rate of switch into mania or hypomania in any of these studies.

### **Depression Associated With Medical Illness**

Paroxetine has been found to be efficacious in the treatment of depression comorbid with several medical disorders, including rheumatoid arthritis, irritable bowel syndrome, cardiovascular disease, and Parkinson's disease ([Bird and Broggin 2000](#); [Masand et al. 2001](#); [Richard et al. 2012](#); [Roose et al. 1998](#)). Paroxetine also was demonstrated to be efficacious in the prevention of interferon- $\alpha$ -induced depression in patients with malignant melanoma ([Figure 12-2](#)) ([Musselman et al. 2001](#)).

**FIGURE 12-2.** Paroxetine effect on interferon- $\alpha$  (IFN- $\alpha$ )-induced depression.

## Depression in Children and Adolescents

In 2003, the FDA released a statement regarding a possible increased risk of suicidal thinking and suicide attempts in children and adolescents 18 years old and younger who are treated with paroxetine for major depressive disorder ([U.S. Food and Drug Administration 2004](#)). The statement was based on data from three well-controlled unpublished studies, each showing no benefit for paroxetine above placebo in the treatment of pediatric depression. The data also revealed an increased rate of suicidal ideation and suicide attempts with paroxetine treatment versus placebo (3.4% vs. 1.2%). Published data on paroxetine have also shown limited efficacy in this population ([Emslie et al. 2006](#); [Keller et al. 2001](#)). A recent reanalysis of Keller et al. found that the benefits of paroxetine were lower and the risks greater than had been reported in the initial publication. In particular, paroxetine did not show greater efficacy than placebo and was associated with increased risks, including suicidal ideation and behavior ([Le Noury et al. 2015](#)).

Differences in pharmacokinetics between children and adults may explain the observed age-related discrepancies in efficacy and suicide risk. In children, an increase in dosage from 10 mg to 20 mg results in a sixfold increase in

serum paroxetine levels ([Findling et al. 1999](#)). This dramatic increase in pediatric serum levels could conceivably trigger activation, akathisia, or disinhibition, potentially explaining the emergence of suicidal thinking or behavior ([Brent 2004](#)), and the effect would be even greater in children who are poor CYP2D6 metabolizers (roughly 10% of the Caucasian population) ([Riddle 2004](#)). Additionally, paroxetine has a relatively short half-life (11 hours vs. 5 days with fluoxetine), and limited treatment adherence—not uncommon in children and teens—could lead to SSRI discontinuation syndrome and dysphoria ([Brent 2004](#)).

Studies utilizing animal models have confirmed these observations. In a rat model, depressive symptoms appear with an increase in locus coeruleus (LC) activity, and effective antidepressant treatment decreases LC activity; however, in younger rats, administration of paroxetine initially increases LC activity, which then declines with prolonged administration ([West et al. 2010](#)). Furthermore, increased LC activity is also associated with low or decreasing serum paroxetine levels, further supporting the hypothesis that poor adherence to or faster metabolism of medication may contribute to the risk of suicidality ([West et al. 2010](#)).

The FDA's black box warning concerning antidepressant use and suicidality risk in children and adolescents has led to a decline in SSRI prescribing for the under-18 age group ([Nemeroff et al. 2007](#)). The [Centers for Disease Control and Prevention \(2007\)](#) reported that suicide rates in American children and adolescents increased 18% in 2004, after 10 years of steady decline. A cohort study of 20,906 adolescents (ages 10–18 years) prescribed SSRIs in British Columbia, Canada, demonstrated a risk of suicidal behavior

(attempted or completed suicide) five times higher than that in the general population; however, the authors noted that this increased rate likely reflects the risk associated with a diagnosis of depression ([Schneeweiss et al. 2010a](#)). Most of the suicidal events occurred during the first 6 months of SSRI treatment. Interestingly, the authors found no significant difference in risk of suicidal behavior among the specific SSRIs evaluated (fluoxetine, citalopram, fluvoxamine, paroxetine, and sertraline) ([Schneeweiss et al. 2010a](#)).

## Panic Disorder

Paroxetine was the first SSRI to be granted FDA approval for the treatment of panic disorder. Paroxetine and clomipramine have been shown to be equally efficacious in the treatment of panic attacks, and a faster onset of action was noted with paroxetine ([Lecrubier et al. 1997a](#)). Paroxetine's long-term efficacy and tolerability have also been demonstrated in patients with panic disorder ([Lecrubier et al. 1997b](#); [Nardi et al. 2012](#)). The combination of cognitive-behavioral therapy and paroxetine is more effective in the treatment of panic disorder than cognitive-behavioral therapy alone ([Bakker et al. 1999](#); [Oehrberg et al. 1995](#)).

In general, patients with panic disorder should be treated initially with a low dosage of paroxetine (e.g., 10 mg/day), with gradual increases in dosage as clinically indicated. The data that led to FDA approval suggested that 40 mg/day was the minimum effective dosage for this condition; however, clinical experience has shown that lower dosages may be sufficient in some patients and higher dosages may

be required in other patients ([Ballenger et al. 1998](#)). The standard duration of treatment ranges from 6 to 12 months; however, rates of relapse for panic disorder appear to be greater than those for major depressive disorder, suggesting that panic disorder may require an indefinite course of treatment ([Hirschfeld 1996](#)).

## Social Anxiety Disorder (Social Phobia)

Paroxetine, sertraline, fluvoxamine CR, and venlafaxine XR are the only medications with FDA approval for the treatment of social anxiety disorder (also called social phobia). Paroxetine's efficacy in the treatment of social anxiety disorder was first suggested by results from open clinical trials ([Mancini and Ameringen 1996](#); [Stein et al. 1996](#)) and was later confirmed by findings from double-blind, placebo-controlled studies ([Baldwin et al. 1999](#); [Stein et al. 1998](#)). Paroxetine and venlafaxine XR have been shown to be similarly effective and superior to placebo in the treatment of social anxiety disorder ([Liebowitz et al. 2005](#)).

In children and adolescents (ages 8–17 years) with social anxiety disorder, paroxetine was found to be superior to placebo ([Wagner et al. 2004](#)). It is important to note that a total of five patients in the paroxetine group ( $n=163$ ), versus none in the placebo group ( $n=156$ ), exhibited suicidal threats or gestures.

It appears that the optimal daily dosage of paroxetine for the treatment of social anxiety disorder is 20–40 mg, with no additional benefit seen for 60 mg ([Lydiard and Bobes 2000](#)). In patients who respond to paroxetine, it is also

advisable to continue treatment to prevent relapse ([Stein et al. 2002](#)).

## Generalized Anxiety Disorder

Venlafaxine XR, escitalopram, duloxetine, and paroxetine have all been approved by the FDA for treatment of generalized anxiety disorder. The first published study supporting the use of paroxetine in generalized anxiety disorder compared it with both imipramine and 2'-chlorodesmethyldiazepam, a benzodiazepine ([Rocca et al. 1997](#)). Not surprisingly, patients receiving the benzodiazepine showed the earliest improvement in symptoms; however, both paroxetine and imipramine produced significant reductions in Hamilton Anxiety Scale (Ham-A) total score, exceeding the reductions produced by the benzodiazepine by week 4 of the 8-week trial. Subsequent studies further confirmed the efficacy of paroxetine in treatment of generalized anxiety disorder ([Bielski et al. 2005](#); [Pollack et al. 2001](#); [Rickels et al. 2003](#)).

Long-term treatment of generalized anxiety disorder with paroxetine may be necessary ([Stocchi et al. 2003](#)). Clinical experience and investigative research indicate that the usual effective paroxetine dosage for treating generalized anxiety disorder is 20 mg/day (GlaxoSmithKline [2001](#)).

## Obsessive-Compulsive Disorder

Currently, the SSRIs fluvoxamine, fluoxetine, sertraline, and paroxetine are FDA approved for the treatment of OCD in adults. Although two meta-analyses assessing the efficacy and tolerability of the TCA clomipramine and SSRIs in OCD

seemed to favor clomipramine in terms of overall effectiveness ([Greist et al. 1995](#); [Piccinelli et al. 1995](#)), the only placebo-controlled multicenter study to compare clomipramine directly against an SSRI (paroxetine) revealed equal efficacy, with greater tolerability for paroxetine ([Zohar and Judge 1996](#)).

Paroxetine also has demonstrated efficacy in pediatric OCD. In a randomized, double-blind, placebo-controlled multicenter trial ([Geller et al. 2004](#)), paroxetine was found to be an effective and generally well-tolerated treatment for OCD in children and adolescents. Patients with comorbid major depressive disorder were excluded from this study, and only one incident of treatment-emergent suicidal behavior or ideation was reported.

In adults, paroxetine daily dosages of  $\geq 60$  mg are usually required for optimal efficacy in OCD. Although patients usually respond to treatment within 3–4 weeks, clinical improvement may not be discernible until 10–12 weeks; therefore, a standard trial of up to 12 weeks should be conducted before an alternative medication is considered ([Rasmussen et al. 1993](#)).

## Posttraumatic Stress Disorder

Among the SSRIs, sertraline and paroxetine have received FDA approval for the treatment of PTSD. Compared with placebo, paroxetine (20–40 mg/day) has been shown to produce significant improvements in the three symptom cluster groups of reexperiencing, avoiding/numbing, and hyperarousal and to reduce disability and depression ([Marshall et al. 1998, 2001](#)). OCD patients with comorbid major depressive disorder respond just as favorably as do

subjects without depression. Similar findings have been reported by other groups ([Tucker et al. 2001, 2004](#)), and paroxetine has also shown efficacy in combination with prolonged exposure therapy ([Schneier et al. 2012](#)) and in long-term treatment ([Kim et al. 2008](#); [Vermetten et al. 2003](#)). A recent study found that paroxetine was less effective than prolonged exposure in achieving symptom remission, and the combination of paroxetine and prolonged exposure was not superior to prolonged exposure alone ([Popiel et al. 2015](#)).

## Premenstrual Dysphoric Disorder

Fluoxetine, sertraline, and paroxetine are FDA approved for the treatment of PMDD. The somatic features of PMDD—bloating, weight gain, breast tenderness, poor concentration, and disturbed sleep and appetite—manifest in the luteal phase of ovulation and disappear with the onset of menstruation. These symptoms are cyclical, predictably appearing prior to each menses ([Dimmock et al. 2000](#)). The psychological symptoms of PMDD are more severe and prominent and include irritability, dysphoria, tension, and mood lability. Paroxetine has been shown to be significantly more effective than the tetracyclic maprotiline, a norepinephrine reuptake inhibitor, in reducing both psychological and somatic symptoms of PMDD ([Eriksson et al. 1995](#)). Two small open trials reported positive findings with paroxetine treatment ([Sundblad et al. 1997](#); [Yonkers et al. 1996](#)), and a double-blind, placebo-controlled study demonstrated that paroxetine CR (25 mg/day) was both well tolerated and effective in the treatment of PMDD ([Cohen et al. 2004](#)).

PMDD can be successfully managed with intermittent luteal-phase dosing, in which the medication is started 14 days before the estimated next menses and continued until the onset of menstruation ([Steiner et al. 2005](#)). It has been shown that paroxetine improves irritability within 14 hours of taking the first dose ([Landén et al. 2009](#)). Both luteal- and continuous-phase dosing of paroxetine (either the CR or the IR formulation) are superior to placebo in relieving the psychological symptoms of PMDD but not the somatic symptoms (food craving, breast tenderness) ([Steiner et al. 2005, 2008](#)). Somatic symptoms may be better addressed with continuous treatment ([Landén et al. 2007](#); [Wu et al. 2008](#)); however, with intermittent dosing, patients experience fewer adverse effects ([Steiner et al. 2008](#)).

## Menopausal Vasomotor Symptoms

In addition to its proven efficacy in PMDD, paroxetine has been found to be efficacious in treating perimenopausal hot flashes ([Simon et al. 2013](#); [Soares et al. 2008](#); [Stearns et al. 2003](#)). In 2013, a new formulation—paroxetine mesylate 7.5-mg capsules, marketed as Brisdelle—became the first nonhormonal medication to receive FDA approval for this indication. The mechanism of action may involve a paroxetine-induced increase in BDNF plasma levels ([Cubeddu et al. 2010](#)).

Earlier studies also demonstrated paroxetine (20 mg/day) to be effective in the treatment of postmenopausal hot flashes in breast cancer survivors with chemotherapy-induced ovarian failure ([Stearns et al. 2000, 2005](#); [Weitzner et al. 2002](#)). However, it is important to consider the risks of paroxetine in women with estrogen receptor-positive

breast cancer who are taking tamoxifen to decrease the risk of breast cancer relapse. Tamoxifen is a prodrug that requires CYP2D6 metabolism to create the more active metabolite endoxifen; however, as a potent inhibitor of CYP2D6, paroxetine blocks the conversion of tamoxifen to endoxifen ([Kelly et al. 2010](#)). An increased risk of death from breast cancer has been observed in women taking tamoxifen and paroxetine ([Kelly et al. 2010](#)).

## Side Effects and Toxicology

---

The popularity of SSRIs as a class in the treatment of psychiatric disorders is owed not to their superiority in efficacy over their predecessors but rather to their overall tolerability and safety. The most commonly cited adverse experiences in patients treated with paroxetine are, in order of frequency, nausea, headache, somnolence, dry mouth, asthenia, sweating, constipation, dizziness, and tremor ([Boyer and Blumhardt 1992](#)).

According to the worldwide preregistration clinical trial database, anticholinergic side effects, tremor, dizziness, postural hypotension, and somnolence were more common in comparison drugs (generally TCAs) ([Jenner 1992](#)). The most common side effect associated with early termination for paroxetine was nausea. Clinical experience demonstrates that this effect can be mitigated with a conservative starting dosage and administration with food, as well as with the use of the CR form of the compound ([Golden et al. 2002](#)). Furthermore, patients reported that nausea diminishes markedly with prolonged administration ([Jenner 1992](#)). As noted earlier, elderly patients do not

appear to be more susceptible than younger patients to the side effects of paroxetine, and cognitive function remains intact or improves during treatment ([Cassano et al. 2002](#); [Nebes et al. 1999](#)).

## Sexual Side Effects

All SSRIs and SNRIs have been associated with male and female sexual dysfunction. In a comparison study of 200 subjects, paroxetine treatment was associated with higher rates of anorgasmia in women and ejaculation difficulty or impotence in men compared with fluoxetine, fluvoxamine, and sertraline ([Montejo-González et al. 1997](#)). In a large cross-sectional observational study ([Clayton et al. 2002](#)), paroxetine was associated with the highest rates of sexual dysfunction among the antidepressants evaluated (mirtazapine, venlafaxine, sertraline, citalopram, fluoxetine, nefazodone, and bupropion).

On the other hand, the sexual side effects of paroxetine have been capitalized on in the treatment of premature ejaculation. Paroxetine produces a greater delay in time to ejaculation compared with fluoxetine, fluvoxamine, sertraline, dapoxetine (a short-acting SSRI awaiting FDA approval for the treatment of premature ejaculation), and mirtazapine ([Safarinejad 2006](#); [Waldinger et al. 1998, 2003](#)).

Sexual side effects emerge in a dose-dependent fashion and do not appear to diminish with prolonged administration; however, the effect is reversible, with most patients returning to normal functioning within 1 month of discontinuing the medication ([Tanrikut et al. 2010](#)). Strategies to lessen the impact of psychotropic medications

on sexual function include reducing the dosage, changing to a different antidepressant with less sexual side-effect liability, and adding an agent (e.g., sildenafil, yohimbine, buspirone, cyproheptadine, amantadine, methylphenidate, bupropion) to reverse the sexual side effects ([Rosen et al. 1999](#)). Ephedrine, an  $\alpha$ - and  $\beta$ -adrenergic receptor agonist previously shown to enhance genital blood flow in women, has been evaluated in women experiencing SSRI-induced sexual dysfunction from paroxetine, sertraline, or fluoxetine ([Meston 2004](#)). Both ephedrine and placebo improved self-reported scores of desire and orgasm intensity compared with baseline, although women taking sertraline or paroxetine fared better than did women taking fluoxetine, a finding the authors attributed to differences in the mechanism of action of these SSRIs ([Ahrold and Meston 2009](#)).

## Suicidality

As previously discussed (see “Depression in Children and Adolescents” subsection earlier in this chapter), in 2004 the FDA ordered pharmaceutical companies to place a black box warning on the package insert for all antidepressants, stating that suicidal behavior might increase in children and adolescents taking these medications. Concerns about a link between antidepressant usage and suicidal ideation led FDA regulators to request that antidepressant manufacturers examine their databases for similar findings in adults. GlaxoSmithKline conducted a meta-analysis of its clinical data comparing suicidality with paroxetine (Paxil/Seroxat) versus placebo. Among depressed patients taking paroxetine, 0.32% (11 of 3,455) attempted suicide,

compared with 0.05% (1 of 1,978) of depressed patients taking placebo, an odds ratio of 6.7 ([GlaxoSmithKline 2006](#)). Cases of completed suicide in both samples were exceedingly rare, with one reported in the paroxetine sample versus none reported with placebo. GlaxoSmithKline further examined the data to identify clinical features of those patients who developed suicidal behavior ([Kraus et al. 2010](#)). Common features among these patients included some improvement in depressive symptoms, younger age (<30 years old), psychosocial stressor preceding the attempt, and no identified suicidality at the prior study visit ([Kraus et al. 2010](#)).

Another analysis of both published and unpublished data on paroxetine in the treatment of depression evaluated suicidality as a secondary outcome ([Barbui et al. 2008](#)), finding an odds ratio of 2.55, with a number needed to harm of 142. The authors noted that whereas suicidality is exceedingly rare, the data are also variably recorded, making it difficult to track this outcome through retrospective reports ([Barbui et al. 2008](#)). As noted earlier, a recent reanalysis of a published GlaxoSmithKline study of paroxetine treatment of child and adolescent depression ([Keller et al. 2001](#)) concluded that the risk of suicidal ideation and suicidal behavior associated with paroxetine was greater than had initially been reported ([Le Noury et al. 2015](#)).

A retrospective cohort study of 36,842 children and adolescents ages 6–18 years initiating treatment with an antidepressant found no differences in risk of suicide attempts among commonly prescribed SNRIs and SSRIs, including paroxetine ([Cooper et al. 2014](#)). Another cohort study of 287,543 adult residents of British Columbia ages 18 years and older who were receiving antidepressants

([Schneeweiss et al. 2010b](#)) found no significant differences in suicidality risk among individual SSRIs (fluoxetine, citalopram, fluvoxamine, paroxetine, and sertraline). As in the study of children and adolescents mentioned earlier ([Schneeweiss et al. 2010a](#); see the subsection “Depression in Children and Adolescents”), most of the suicidal events occurred during the first 6 months of treatment ([Schneeweiss et al. 2010b](#)). A retrospective study of 502,179 U.S. Department of Veterans Affairs patients with depression diagnoses who initiated antidepressant treatment found evidence suggesting a lower risk of suicide death with fluoxetine and sertraline compared with paroxetine, although the authors noted that this finding differed according to which data analysis technique was used ([Valenstein et al. 2012](#)).

A limitation of findings regarding the link between paroxetine and suicidality is that the placebo-controlled studies included in meta-analyses did not have suicidal ideation and self-harming behaviors as main outcome measures. Procedures for assessing suicidality have not, until recently, been standardized and are based largely on unsolicited and unstructured reports and observations. Also, depression is a risk factor for suicidal behavior, and suicide is a potential complication of the disease. Transient suicidal thinking must be considered in the context of the overall risk-benefit analysis of paroxetine in the treatment of adults with major depressive disorder.

Nevertheless, in late 2006, an FDA advisory panel extended the black box warning to cover young adults up to their mid-20s ([U.S. Food and Drug Administration 2007](#)). The advisory panel reported that in patients 18–24 years of age, antidepressant use was associated with 4 cases of suicidal ideation per 1,000 patients treated, that there was

no evidence of increased risk in adults older than 24 years, and that antidepressant treatment was unequivocally protective against suicidality in patients 65 years and older.

Clinicians should inform their patients about the possible risks and should monitor depressed patients closely when paroxetine or any other antidepressant is prescribed, particularly during the early phase of treatment. The FDA advisory committee has made it clear that the black box warning should not dissuade physicians from prescribing antidepressants to patients in need ([U.S. Food and Drug Administration 2007](#)).

## Medical Safety

Paroxetine treatment in clinical trials has not been associated with any significant abnormalities in standard laboratory tests, including hematological indices and chemistry panels, electroencephalogram (EEG), or electrocardiogram (ECG). One possible concern regarding paroxetine had been its potential for decreasing heart rate variability, which is a significant risk factor for myocardial infarction and cardiovascular mortality ([Carney et al. 2005](#)). Other norepinephrine reuptake-inhibiting antidepressants have been shown to cause decreases in this electrophysiological variable ([Rechlin 1994](#)), and depressed patients have been shown to exhibit lower heart rate variability than nondepressed persons ([Gorman and Sloan 2000](#)); however, paroxetine does not exhibit this effect. A review of the literature also determined that paroxetine may have the lowest risk of QT prolongation among the SSRIs ([Funk and Bostwick 2013](#)).

Paroxetine and other SSRIs have been implicated in precipitation of the syndrome of inappropriate antidiuretic hormone (SIADH), particularly in elderly individuals; symptoms resolve on discontinuation of the medication ([Strachan and Shepherd 1998](#)). One study demonstrated that hyponatremia (defined as plasma sodium levels  $<135$  mEq/L) occurred in 12% (9 of 75) of subjects, typically within the first 10 days of paroxetine treatment ([Fabian et al. 2004](#)). Risk factors for developing hyponatremia were low body mass index and low baseline plasma sodium levels.

## Discontinuation Syndrome

With abrupt discontinuation or treatment interruption, patients may develop what has become known as the SSRI discontinuation syndrome. Symptoms (such as dizziness, paresthesias, agitation, anxiety, nausea, and sweating) occur as early as the second day after a missed dose and may persist for several days. A comparison of SSRI postmarketing safety data found that withdrawal-related events occurred more frequently in paroxetine-treated patients than in patients treated with sertraline, fluvoxamine, or fluoxetine and that these events had a mean duration of 10.2 days ([Price et al. 1996](#)); similar results were reported by other groups ([Michelson et al. 2000](#); [Montgomery et al. 2004](#); [Rosenbaum et al. 1998](#)). Studies examining the effect of shorter SSRI treatment interruptions (3–5 days)—similar to what a patient would experience if he or she missed just a few medication doses—found that whereas paroxetine-treated patients develop significant discontinuation-emergent effects, fluoxetine-treated patients do not, a disparity likely due to differences

in the half-lives of these medications ([Judge et al. 2002](#); [Michelson et al. 2000](#)).

To prevent the emergence of withdrawal symptoms, practitioners are advised to gradually taper the dosage when discontinuing paroxetine in their patients. Despite the potential for withdrawal reactions after abrupt discontinuation of paroxetine, there is no clinical evidence of dosage escalation, craving, or drug-seeking behavior associated with dependence or addiction ([Inman et al. 1993](#); [Johnson et al. 1998](#); [Sharma et al. 2000](#)).

## Overdose

Overdoses with paroxetine are rarely associated with morbidity or mortality, which is in sharp contrast to the situation with the TCAs or venlafaxine ([Cheeta et al. 2004](#); [Whyte et al. 2003](#)). In the clinical trials program prior to FDA registration of paroxetine, 16 patients had ingested an overdose (doses of up to 850 mg of paroxetine); all patients recovered uneventfully ([Jenner 1992](#)). An extensive review of the literature (including adverse events databases) revealed a total of 28 fatalities involving paroxetine overdoses; however, in nearly all cases, either coingestants were involved or causality could not be ascertained ([Barbey and Roose 1998](#)).

## Use During Pregnancy and Lactation

A more complete discussion of the use of psychotropic medications during pregnancy appears elsewhere in this volume (see [Chapter 57, “Psychopharmacology During Pregnancy and Lactation”](#)); however, because paroxetine is

the only SSRI to be allocated to FDA pregnancy category D (“There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks”), it warrants specific discussion here.

Spontaneous abortion has been linked both to depression and to antidepressant use; the risk may be even greater for women who are treated with paroxetine or venlafaxine ([Nakhai-Pour et al. 2010](#)).

Compared with other SSRIs, paroxetine has lower transmission across the placenta, and cord blood concentrations do not correlate with maternal dosing ([Hendrick et al. 2003b](#)). Maternal CYP2D6 polymorphisms appear to affect the pharmacokinetics of paroxetine. Women characterized as extensive metabolizers show decreases in paroxetine plasma levels over the course of pregnancy, whereas women characterized as intermediate or poor metabolizers show increased paroxetine levels ([Ververs et al. 2009](#)). It is possible that this effect may translate to a greater risk of fetal teratogenicity for women who are poor or intermediate metabolizers ([Ververs et al. 2009](#)).

Teratogenicity is a major concern when prescribing medications to women of childbearing age. The results of an unpublished study by GlaxoSmithKline (Paxil) led the FDA to warn that paroxetine may increase the risk of major congenital malformations (GlaxoSmithKline [2005](#)). Several organ systems, including the gastrointestinal, genitourinary, and central nervous systems, were affected; the most common cardiovascular anomalies were ventricular septal defects. A meta-analysis, also completed by GlaxoSmithKline, found a prevalence odds ratio of 1.46 for

combined cardiac defects with exposure to paroxetine in the first trimester. Considering a background prevalence of cardiac defects in the unexposed population of 1%, this would represent a 50% increase for the paroxetine-exposed population (Wurst et al. 2010).

A cohort study comparing rates of major congenital malformations in infants born to women treated with paroxetine, fluvoxamine, or sertraline during pregnancy found no significant differences among the medication groups compared with the control group (Kulin et al. 1998). In another study comparing birth outcomes after prenatal exposure to paroxetine, fluoxetine, or sertraline, rates of neonatal complications and congenital malformations in antidepressant-exposed infants were lower (1.4%) than rates in the general population, with no significant differences among medications (Hendrick et al. 2003a). Whereas one prospective controlled observational study found no increased risk of cardiac defects with paroxetine exposure (Diav-Citrin et al. 2008), a case-control study of data from a population-based registry of birth defects in the Netherlands did find an increased risk of atrial septal defects with first-trimester paroxetine exposure (adjusted odds ratio=5.7, 95% confidence interval=1.4-23.7) (Bakker et al. 2010). A recent meta-analysis of 23 studies concluded that paroxetine exposure during the first trimester was associated with a significantly increased risk of major congenital malformations, particularly major cardiac malformations (Bérard et al. 2016). It is important to note that studies of teratogenicity are frequently complicated by the effects of depression itself or of polypharmacy (e.g., concurrent use of benzodiazepines) (Yonkers et al. 2009). Nevertheless, on the basis of the risk of malformations, the American College of Obstetricians and Gynecologists

(ACOG) has recommended that paroxetine be avoided, if possible, in pregnant women or women planning pregnancy ([ACOG Committee on Practice Bulletins—Obstetrics 2008](#)).

Clinical studies of paroxetine in the setting of pregnancy suggest that gestational exposure might have transient negative effects on the newborn infant, particularly if the mother is treated during the third trimester. Infants with third-trimester paroxetine exposure show significantly increased distress compared with infants not so exposed ([Costei et al. 2002](#)). Symptoms in neonates exposed to SSRIs in utero include tremor, hypertonicity, irritability, weak or absent cry, seizures, and poor feeding; these symptoms typically resolve within 2 weeks ([Knoppert et al. 2006](#); [Yonkers et al. 2009](#)). Debate continues among neonatologists as to whether this neonatal distress represents a manifestation of serotonin excess or serotonin withdrawal ([Laine et al. 2004](#); [Stiskal 2005, 2006](#)).

Although not specific to paroxetine, an issue that has received much media attention is the development of persistent pulmonary hypertension of the newborn (PPHN) in neonates exposed to SSRIs late (>20 weeks) in gestation. A rare condition associated with significant morbidity, PPHN has an estimated base rate in the United States of 1–2 per 1,000 births ([Andrade et al. 2009](#)). A large case-control epidemiological study found an odds ratio of developing PPHN of 6.1 for infants exposed to SSRIs after gestational week 20 ([Chambers et al. 2006](#)). However, a more recent retrospective review did not find a significant difference in risk of developing PPHN with exposure to SSRIs; in fact, the authors found a higher prevalence in the nonexposed group ([Andrade et al. 2009](#)).

If a woman opts to continue antidepressant treatment during pregnancy, the clinician is advised to monitor for

relapse, given that higher dosages are often needed, especially in the early third trimester, to achieve or maintain disease remission ([Hostetter et al. 2000](#)).

Paroxetine is secreted into breast milk, with greater concentrations found in hindmilk than foremilk ([Ohman et al. 1999](#); [Stowe et al. 2000](#)). However, in a study in which the sera of nursing infants were analyzed for the presence of paroxetine after 10 days of maternal treatment with paroxetine at a stable daily dosage of 10–50 mg, the drug was undetectable in all infants ([Stowe et al. 2000](#)). A literature review concluded that paroxetine and sertraline have a better safety profile in breast-feeding women compared with other SSRIs and SNRIs ([Orsolini and Bellantuono 2015](#)).

---

## Drug-Drug Interactions

---

As noted previously (see “Pharmacokinetics and Disposition” section earlier in chapter), paroxetine is dependent primarily on the CYP2D6 hepatic enzyme for conversion into its inactive metabolites ([Hiemke and Härter 2000](#)). Paroxetine is not only a substrate of this system but also an inhibitor; therefore, other drugs that are metabolized by CYP2D6 are potentially subject to decreased clearance and subsequent increased plasma concentrations ([Sindrup et al. 1992b](#)). Concern is greatest for potential drug-drug interactions when the medication in question has a low therapeutic index. ([Table 12-1](#) lists potentially important drug-drug interactions involving paroxetine.)

---

**TABLE 12-1. Clinical significance of potential drug-drug interactions involving paroxetine**

Monoamine oxidase inhibitors	Clinically significant
Tamoxifen	Clinically significant
Tricyclic antidepressants	Clinically significant
Antiepileptic agents	Probably significant
$\beta$ -Adrenergic receptor antagonists	Probably significant
Cimetidine	Probably significant
Type IC antiarrhythmics	Probably significant
Typical antipsychotics	Possibly significant
Warfarin	Possibly significant
Clozapine	Inconclusive
Digoxin	Not clinically significant
Lithium	Not clinically significant

Medications that are CYP2D6 dependent include many antipsychotics, TCAs, type Ic antiarrhythmics,  $\beta$ -adrenergic agents, trazodone, and dextromethorphan ([Nemeroff et al. 1996](#)). Most reports of interactions between these medications and paroxetine are published as case reports ([Lane 1996](#)). As discussed earlier (see the subsection “Menopausal Vasomotor Symptoms”), the breast cancer medication tamoxifen is converted to its active metabolite by CYP2D6, and there is evidence that paroxetine decreases the efficacy of tamoxifen and increases mortality in women with breast cancer who are taking tamoxifen ([Kelly et al. 2010](#)).

Paroxetine does not appear to potentiate the sedative effects of haloperidol ([Cooper et al. 1989](#)); however, dystonia has been reported with the combination ([Budman et al. 1995](#)). In one prospective study, clozapine serum levels increased by an average of 40% when clozapine was coadministered with SSRIs, including paroxetine at a mean dosage of 31.2 mg/day ([Centorrino et al. 1996](#)). In another study that used a lower dosage of paroxetine (20 mg/day), no significant increase in clozapine concentrations was noted ([Wetzel et al. 1998](#)). There is insufficient evidence to draw conclusions about the clinical significance of interactions between paroxetine and other second-generation antipsychotics ([Spina and de Leon 2014](#)). Case reports have described possible exaggeration of extrapyramidal side effects when paroxetine was coadministered with perphenazine ([Ozdemir et al. 1997](#)), molindone ([Malek-Ahmadi and Allen 1995](#)), or pimozide ([Horrigan and Barnhill 1994](#)).

Paroxetine was found to increase total exposure (i.e., area under the curve of plasma concentrations) to the  $\beta$ -adrenergic receptor antagonist nebivolol by a factor of 6.1 ([Briciu et al. 2014](#)). Paroxetine also increased plasma concentrations of the  $\beta$ -adrenergic receptor antagonist timolol (administered as eye drops) to a level that could cause systemic adverse events in at-risk patients ([Mäenpää et al. 2014](#)).

Paroxetine is highly protein bound and has the potential to increase free drug levels of other medications that are bound to plasma proteins, such as warfarin, lithium, and digoxin, although this effect is rarely clinically meaningful ([Bannister et al. 1989](#); [Haenen et al. 1995](#); [Preskorn 1993](#)).

In prospective studies involving valproate, carbamazepine, or phenytoin, coadministration with

paroxetine did not cause any significant changes in plasma levels of these drugs ([Andersen et al. 1991](#); [Kaye et al. 1989](#)). By contrast, both phenytoin and carbamazepine have been shown to decrease plasma paroxetine concentrations ([Hiemke and Härtter 2000](#); [Kaye et al. 1989](#)). Valproate also may increase plasma paroxetine concentrations ([Andersen et al. 1991](#)). Cimetidine, which is a potent inhibitor of the CYP2D6 isoenzyme, has been shown to result in a 50% elevation of paroxetine concentrations ([Bannister et al. 1989](#)). The clinical significance of these variations in paroxetine concentrations is minor because of the wide interindividual pharmacokinetic variability, high therapeutic index, and lack of a concentration–efficacy relationship with paroxetine ([Gunasekara et al. 1998](#)).

Paroxetine does not potentiate the psychomotor effects of amobarbital, oxazepam, diazepam, or alcohol ([Bannister et al. 1989](#); [Cooper et al. 1989](#)).

Combinations of medications that enhance serotonergic activity may result in serotonin toxicity (serotonin syndrome), manifesting as agitation, myoclonus, hyperreflexia, diarrhea, diaphoresis, delirium, fever, and possibly death ([Weiner et al. 1997](#)). Concomitant use of MAOIs with any of the SSRIs is absolutely contraindicated, and a washout period of 14 days is recommended when switching from one agent to another ([Gunasekara et al. 1998](#); [Weiner et al. 1997](#)). Evidence of serotonin toxicity has been documented in case reports describing coadministration of paroxetine with moclobemide ([Hawley et al. 1996](#)), nefazodone ([John et al. 1997](#)), dextromethorphan ([Skop et al. 1994](#)), imipramine ([Weiner et al. 1997](#)), trazodone ([Reeves and Bullen 1995](#)), or other agents. The combination of SSRIs and sumatriptan, a 5-

HT<sub>1D</sub> receptor agonist used in the treatment of migraine, was previously discouraged because of the theoretical risk of precipitation of serotonin toxicity; however, a series of six cases, one involving paroxetine, of concurrent sumatriptan and SSRI administration demonstrated no such adverse events ([Leung and Ong 1995](#)).

## Conclusion

---

Paroxetine has been demonstrated to be an effective treatment for several psychiatric disorders, including major depressive disorder and virtually all of the anxiety disorders, as well as OCD and PTSD. It is well tolerated, with convenient once-daily dosing, and it is available in both IR and CR formulations. Most patients can expect symptomatic relief within 4 weeks, and some patients respond as early as 2 weeks. With few exceptions, the potential for serious pharmacokinetic interactions with other drugs is low, although concomitant MAOI use is contraindicated and use with tamoxifen in women with breast cancer may increase mortality. Overdosage rarely results in significant toxicity. Along with other SSRIs, initiation of paroxetine has been linked to an increase in suicidal ideation and suicidal behavior, primarily in children and adolescents. Paroxetine should be used cautiously in the treatment of pediatric anxiety disorders. Other SSRIs should be considered over paroxetine in pregnancy because of evidence for an association with congenital malformations. In the postpartum setting, however, nursing very likely poses a negligible exposure risk to infants of mothers receiving treatment with paroxetine.

Paroxetine, with its wide application and favorable safety profile, represents an important member of the SSRI class. It continues to be evaluated for efficacy in the treatment of other psychiatric and nonpsychiatric disorders.

# CHAPTER 13

## Fluvoxamine

Elias Aboujaoude, M.D.

Lorin M. Koran, M.D.

Fluvoxamine is a member of the selective serotonin reuptake inhibitor (SSRI) family of drugs. Initially manufactured by Duphar Laboratories in the United Kingdom in 1971, fluvoxamine was registered as an antidepressant in Switzerland in 1983, becoming the first drug in the now hugely popular SSRI class to reach the market. Since its introduction, fluvoxamine has undergone a wide range of trials to assess its therapeutic potential in depression, several anxiety disorders, and obsessive-compulsive disorder (OCD). Fluvoxamine has been available in the United States since 1994, when it received U.S. Food and Drug Administration (FDA) approval for the treatment of OCD ([Ware 1997](#)). More than 28 million people worldwide have been treated with fluvoxamine ([Buchberger and Wagner 2002](#)).

---

## Structure-Activity Relations

---

Fluvoxamine belongs to the 2-aminoethyl oxime ethers of the aralkyl ketones ([Figure 13-1](#)) and is chemically identified as 5-methoxy-4'-(trifluoromethyl) valerophenone-(E)-O-(2-aminoethyl) oxime maleate (1:1). Fluvoxamine's empirical formula is  $C_{15}H_{21}O_2N_2F_3 \cdot C_4H_4O_4$ , and it does not have a chiral center or exist in stereoisomers. Because of local irritant properties, fluvoxamine cannot be administered parenterally ([Physicians' Desk Reference 2015](#)).

---

## Mechanism of Action

---

Like other SSRIs, fluvoxamine binds to the presynaptic serotonin transporter (SERT) and prevents it from reabsorbing serotonin into the presynaptic terminals. This increases the amount of serotonin in the synaptic cleft. How this increase translates into efficacy remains unclear, but it has been hypothesized to involve downstream effects, including serotonin<sub>1A</sub> (5-HT<sub>1A</sub>) autoreceptor desensitization ([Stahl 1998](#)); increased sensitivity of dopamine<sub>2</sub> (D<sub>2</sub>)-like receptors in the nucleus accumbens ([Gershon et al. 2007](#));

enhanced neurogenesis ([Dranovsky and Hen 2006](#)); changes in mitochondrial production of cerebral adenosine triphosphate (ATP) ([Ferreira et al. 2014](#)); and individual pharmacogenomics factors involving SERT and catechol-*O*-methyltransferase (COMT) gene variants ([Fukui et al. 2014](#); [Mancama and Kerwin 2003](#)). Furthermore, sigma-1 receptors appear to modulate several neurotransmitter pathways, and evidence suggests that fluvoxamine's affinity for the sigma-1 receptor exceeds that of all other SSRIs ([Ishikawa et al. 2007](#)).

---

## Pharmacological Profile

---

Fluvoxamine is a more potent inhibitor of serotonin reuptake than the tricyclic antidepressants, including clomipramine, but is less potent than the other SSRIs. It is highly selective for the serotonin transporter ( $K_i=2.3$  nmol/L) and has minimal affinity for the norepinephrine and dopamine transporters, or the muscarinic,  $\alpha_1$ -adrenergic, histaminic, and 5-HT<sub>2C</sub> receptors. It possesses no monoamine oxidase-inhibiting properties ([Lapierre et al. 1983](#); [Owens et al. 2001](#); [Palmer and Benfield 1994](#); [Ware 1997](#)).

---

## Pharmacokinetics and Disposition

---

Fluvoxamine is almost entirely absorbed from the gastrointestinal tract, regardless of the presence of food

([van Harten 1995](#)). Still, first-pass metabolism limits oral bioavailability to 53% ([DeVane 2003](#); [DeVane and Gill 1997](#)). Peak plasma concentrations occur within 2–8 hours, and steady-state concentration is achieved within 10 days ([van Harten 1995](#)). Plasma concentration shows no consistent correlation with efficacy or side effects, thus limiting the value of monitoring concentration.

The mean half-life of fluvoxamine is 15 hours, making twice-daily dosing preferable. Despite fluvoxamine's relatively short half-life, a discontinuation syndrome is rare ([Buchberger and Wagner 2002](#)), possibly because of the drug's slower elimination from the brain ([Strauss et al. 1998](#)).

Because fluvoxamine is widely distributed and reaches higher concentrations in the brain and other organs than in plasma ([Benfield and Ward 1986](#)), patients receiving hemodialysis do not require replacement doses; re-equilibration should occur ([DeVane and Gill 1997](#)).

Compared with other SSRIs, fluvoxamine's rate of protein binding is relatively low (77%) ([DeVane and Gill 1997](#)), which implies less risk of interactions from drug displacement.

At least 11 products of fluvoxamine metabolism are known, but none seems pharmacologically active ([DeVane and Gill 1997](#); [Palmer and Benfield 1994](#)). Metabolism is thought to occur primarily through oxidative demethylation. Only minimal amounts of fluvoxamine (3%) are excreted unchanged by the kidneys, suggesting that renal impairment should not significantly alter fluvoxamine's pharmacokinetics ([van Harten 1995](#)).

Because hepatic clearance is decreased in patients with liver disease and in elderly patients, dosage adjustments are sometimes necessary ([DeVane and Gill 1997](#); [van](#)

[Harten et al. 1993](#)). No gender-based differences in concentration seem to exist in adults ([DeVane and Gill 1997](#)). Pharmacokinetics studies in children report a higher area under the curve (AUC) than in adolescents, with the difference being more pronounced in females, suggesting lower dosages may be sufficient in children. No appreciable pharmacokinetic differences were observed between adolescents and adults ([Physicians' Desk Reference 2015](#)).

In the United States, fluvoxamine is available in both immediate-release and controlled-release formulations.

---

## Indications and Efficacy

---

### Depression

The first trial of fluvoxamine treatment of depression dates to 1976. Since then, several randomized, single- or double-blind studies conducted have tested fluvoxamine's antidepressant efficacy against placebo, SSRIs, serotonin-norepinephrine reuptake inhibitors, tricyclic antidepressants, tetracyclic antidepressants, and a reversible inhibitor of monoamine oxidase. The trials vary in design but, taken together, support the efficacy and safety of fluvoxamine in treating depression—including psychotic depression—across all age groups ([Fukuchi and Kanemoto 2002](#); [Haffmans et al. 1996](#); [Kiev and Feiger 1997](#); [Otsubo et al. 2005](#); [Rapaport et al. 1996](#); [Rossini et al. 2005](#); [Ware 1997](#); [Zanardi et al. 2000](#); [Zohar et al. 2003](#)). Study durations ranged from 4 to 7 weeks, and dosages ranged from 50 to 300 mg/day. Further, benefits from fluvoxamine

seem to be sustained over at least 1 year ([Terra and Montgomery 1998](#)).

In a well-designed recent analysis of 54 randomized controlled trials ( $N=5,122$ ), no strong evidence was found to indicate that fluvoxamine was either superior or inferior to other antidepressants regarding response and remission ([Omori et al. 2010](#)). However, differing side-effect profiles were evident, especially in regard to more frequent reports of nausea and vomiting for fluvoxamine compared with some other antidepressants.

Finally, because of fluvoxamine's potent sigma-1 agonist action and the putative antipsychotic property such action might confer, some authors have suggested that fluvoxamine monotherapy might be a useful alternative to combined treatment with an antidepressant and an antipsychotic in cases of psychotic depression ([Furuse and Hashimoto 2009](#)).

## Panic Disorder

The largest randomized, double-blind, placebo-controlled study to test fluvoxamine in the treatment of panic disorder involved 188 subjects who were assigned to 8 weeks of fluvoxamine 100–300 mg/day or placebo. At study end, significantly more subjects in the fluvoxamine group were free from panic attacks (69% vs. 46%,  $P=0.002$ ) ([Figgitt and McClellan 2000](#)).

Limited data suggest similar efficacy for fluvoxamine and the tricyclic antidepressant imipramine, as well as a possible potentiating effect of fluvoxamine when combined with cognitive or exposure therapy ([Figgitt and McClellan 2000](#)).

# Social Anxiety Disorder (Social Phobia)

The largest double-blind, placebo-controlled study to assess the effectiveness of fluvoxamine (50–300 mg/day) in social anxiety disorder recruited 92 subjects with social phobia ([Stein et al. 1999](#)). Significantly more subjects assigned to fluvoxamine responded (43% vs. 23%,  $P=0.04$ ), as determined by a rating of much or very much improved on the global improvement item of the Clinical Global Impressions Scale. More recently, a controlled-release formulation of fluvoxamine showed similarly good results in two randomized, double-blind studies ([Davidson et al. 2004](#); [Westenberg et al. 2004](#)). This formulation was approved in the United States in 2008 for the treatment of social anxiety disorder and OCD.

## Obsessive-Compulsive and Related Disorders

### **Obsessive-Compulsive Disorder in Adults**

The first formal test of fluvoxamine in the treatment of OCD took place in 1987 ([Price et al. 1987](#)). Since then, multiple randomized studies have established fluvoxamine's efficacy and safety in treating OCD. These trials have compared fluvoxamine with placebo, clomipramine, and other SSRIs.

In randomized, double-blind comparisons with placebo, subjects were given fluvoxamine 100–300 mg/day for 6–10 weeks. Significant improvements in Yale-Brown Obsessive Compulsive Scale (Y-BOCS) scores were observed, and

response rates ranged from 38% to 52% (vs. 0% to 18% for placebo) ([Figgitt and McClellan 2000](#)).

We identified five published double-blind comparisons of fluvoxamine and clomipramine, both dosed at  $\leq 300$  mg/day, involving a total of 531 subjects and lasting 9–10 weeks ([Figgitt and McClellan 2000](#); [Freeman et al. 1994](#); [Koran et al. 1996](#); [Milanfranchi et al. 1997](#); [Mundo et al. 2000, 2001](#)). All studies demonstrated equal efficacy for the two agents (range of response rates: 56%–85% for fluvoxamine and 53%–83% for clomipramine). One small published study compared fluvoxamine with other SSRIs. This 10-week single-blind study of 30 subjects randomly assigned to fluvoxamine, paroxetine, or citalopram suggested similar efficacy ([Mundo et al. 1997](#)).

Long-term maintenance treatment with fluvoxamine seems to protect against relapse. A 2-year open-label follow-up study enrolling 130 subjects who had responded to fluvoxamine 300 mg/day, clomipramine 150 mg/day, or fluoxetine 40 mg/day showed that maintenance treatment at full or half dosages was significantly superior to treatment discontinuation in preventing relapse ([Ravizza et al. 1996](#)).

Predictors of response to fluvoxamine in OCD were evaluated in a recent functional magnetic resonance imaging (fMRI) study involving 17 subjects who underwent fMRI at baseline and after 12 weeks of treatment (final dose=200 mg/day). Pretreatment hyperactivation of the right cerebellum and left superior temporal gyrus was associated with reduced posttreatment Y-BOCS scores ([Sanematsu et al. 2010](#)).

Another study investigated treatment compliance with fluvoxamine and cognitive therapy. Forty-eight subjects with OCD who had failed to respond to behavioral therapy were

randomly assigned to 12 weeks of either fluvoxamine ( $n=26$ ) or cognitive therapy ( $n=22$ ). Although a higher baseline Y-BOCS score and assignment to cognitive therapy were associated with better compliance, fluvoxamine demonstrated statistically superior improvement compared with cognitive therapy ([Landsheer et al. 2015](#)).

## **Obsessive-Compulsive Disorder in Children and Adolescents**

Fluvoxamine 50–200 mg/day was tested in a 10-week double-blind, placebo-controlled study involving 120 subjects ages 8–17 years with OCD. Response was defined as a reduction of at least 25% in the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) score. Mean scores were significantly lower in the fluvoxamine group as early as week 1 ( $P < 0.05$ ). End-of-study response rates were 42% for the fluvoxamine group versus 26% for the placebo group ( $P=0.065$ ). The most common side effects were insomnia and asthenia ([Riddle et al. 2001](#)).

## **Other Obsessive-Compulsive and Related Disorders**

Three open-label trials of fluvoxamine involving a total of 75 subjects with body dysmorphic disorder reported response rates of 63%–67% ([Perugi et al. 1996](#); [Phillips et al. 1998, 2001](#)).

A 12-week open-label study of fluvoxamine in 21 subjects with trichotillomania produced only minor improvement ([Stanley et al. 1997](#)).

## **Other Addictive or Impulse-Control Disorders**

Like other SSRIs, fluvoxamine has produced inconsistent results when tested in impulse-control disorders or behavioral addictions that are sometimes considered part of the obsessive-compulsive spectrum. Despite encouraging open-label data in compulsive buying disorder ([Black et al. 1997](#)), two double-blind, placebo-controlled studies failed to show benefit over placebo ([Black et al. 2000](#); [Ninan et al. 2000](#)).

Similarly, two small studies in DSM-IV (American Psychiatric Association 1994) pathological gambling suggested that fluvoxamine might be beneficial ([Hollander et al. 1998, 2000](#)). However, a larger 6-month double-blind, placebo-controlled study failed to show separation from placebo ([Blanco et al. 2002](#)).

## Posttraumatic Stress Disorder

Small open-label studies suggest a role for fluvoxamine in treating posttraumatic stress disorder (PTSD) ([Davidson et al. 1998](#); [Figgitt and McClellan 2000](#); [Marmar et al. 1996](#); [Tucker et al. 2000](#)). Twenty-four Dutch veterans of World War II with chronic PTSD showed significant improvement on a PTSD self-rating scale after a 12-week course of fluvoxamine at  $\leq 300$  mg/day ( $P=0.04$ ) ([De Boer et al. 1992](#)). More recently, a 14-week open-label trial of fluvoxamine (100–300 mg/day) in 15 U.S. veterans with combat-related PTSD reported a statistically significant decrease in the Clinician-Administered PTSD Scale (CAPS) total score ( $P<0.001$ ) ([Escalona et al. 2002](#)).

## Eating Disorders

In another study, 72 subjects with bulimia nervosa who had been treated successfully with psychotherapy were randomly assigned to receive fluvoxamine (100–300 mg/day) or placebo and were followed for 12 weeks. Fluvoxamine was significantly superior in preventing relapse ( $P < 0.05$ ) ([Fichter et al. 1996](#)). A small 12-week double-blind, placebo-controlled study in 12 subjects with acute bulimia nervosa suggested that fluvoxamine 200 mg/day was superior to placebo ([Milano et al. 2005](#)).

A 9-week double-blind, placebo-controlled study in 85 subjects with binge-eating disorder found that fluvoxamine (50–300 mg/day) was significantly more effective than placebo in reducing binge frequency ([Hudson et al. 1998](#)).

## Delirium

Delirium, especially in hospitalized older patients, is associated with increased morbidity and mortality, prolonged hospital stays, and cognitive deterioration. Antipsychotic drugs have been widely used for treating delirium but are associated with sedation, extrapyramidal side effects, and cardiac arrhythmias. Furthermore, there is an elevated risk of mortality in older patients treated with atypical antipsychotics. The endoplasmic reticulum protein sigma-1 receptors are thought to play a key role in calcium signaling and cell survival and may regulate a number of neurotransmitter systems implicated in the pathophysiology of delirium. Several recent case reports have suggested that fluvoxamine, because of its potent sigma-1 receptor agonism, may be effective in the treatment of delirium ([Furuse and Hashimoto 2010a, 2010b, 2010c](#)).

# Pain

Preliminary research has explored the potential anti-pain properties of fluvoxamine. An animal study investigated fluvoxamine in the treatment of neuropathic pain in diabetic rats. Experimental animals were given intraperitoneal streptozotocin to induce neuropathic pain, followed by daily oral fluvoxamine. Using the hind paw withdrawal threshold to assess hyperalgesia, researchers concluded that fluvoxamine was associated with decreased pain ([Kato et al. 2013](#)).

More recently, a randomized controlled trial in 120 subjects with cancer accompanied by moderate to severe pain assigned participants to receive flexibly dosed extended-release oxycodone either alone ( $n=60$ ) or in combination with fluvoxamine dosages of 150 mg/day or greater ( $n=60$ ). Individuals in the oxycodone-only group required maximum dosages of extended-release oxycodone of 54 mg/day and 132 mg/day for moderate and severe pain, respectively, compared with 44.7 mg/day and 110 mg/day in the combination group. Subjects who received fluvoxamine augmentation required lower doses of oxycodone, but the difference was statistically significant only for severe pain. Additionally, treatment with fluvoxamine was associated with improved overall quality of life ([Xiao et al. 2014](#)).

---

## Side Effects and Toxicology

---

Data from 34,587 patients enrolled in postmarketing fluvoxamine studies were combined in a database to assess

safety. Dosages ranged from 50 to 300 mg/day taken over 4–52 weeks ([Wagner et al. 1994](#)). Overall, 14% of participants discontinued treatment because of side effects, most frequently nausea and vomiting (4.6% and 1.7%, respectively). The adverse events reported at greater than 5% incidence were nausea, somnolence, and asthenia (15.7%, 6.4%, and 5.1%, respectively). The rate of weight gain was only 1%. Sexual side effects were not mentioned in the analysis (only side effects with >1% incidence were listed), although a separate open-label study designed to assess SSRI-induced sexual dysfunction in men and women showed statistically similar rates for fluvoxamine, fluoxetine, sertraline, and paroxetine (range: 54.4%–64.7%) ([Montejo-González et al. 1997](#)).

Another postmarketing surveillance review covering 17 years ([Buchberger and Wagner 2002](#)) analyzed 6,658 individual reports, including 16,110 adverse drug reactions. The frequency of death was calculated at 0.9 per 100,000 patients. Suicide, mostly by overdose, was the cause of death in nearly half, but only 1.2% of overdoses involved fluvoxamine alone. The rate of suicidality (ideation, attempts, and completed suicides) was estimated at 2.81 events per 100,000 patients. Drug interactions were reported at a rate of 0.85 cases per 100,000 patients, most commonly with clozapine. Cases of switch to mania and discontinuation syndrome were also rare, occurring at rates of 0.47 and 0.38 events per 100,000 patients, respectively. Serotonin syndrome was even less frequent.

A more recent study assessed the cardiac effects of fluvoxamine in beagle dogs ( $n=4$ ). Dogs were administered 0.1 mg/kg of fluvoxamine intravenously, corresponding to the recommended daily oral dose, followed by a second and third dose of 1 mg/kg and 10 mg/kg, respectively. Both

supratherapeutic doses were associated with QT interval prolongation ([Yamazaki-Hashimoto et al. 2015](#)).

Two studies found no consistent treatment-related changes in laboratory values or vital signs in fluvoxamine-exposed subjects ([Wagner et al. 1994](#)).

---

## Drug-Drug Interactions

---

Fluvoxamine is a potent inhibitor of cytochrome P450 (CYP) 1A2. Drugs partially metabolized by CYP1A2 whose levels may rise as a result of fluvoxamine's inhibition of this isozyme include tizanidine, tertiary-amine tricyclic antidepressants (imipramine, amitriptyline, clomipramine), clozapine, tacrine, theophylline, propranolol, and caffeine. Doses of theophylline and clozapine should be reduced if co-administered with fluvoxamine ([DeVane and Gill 1997](#)).

Fluvoxamine also inhibits CYP2C19 and CYP3A4. CYP2C19 metabolizes warfarin, and elevations in warfarin concentration have been reported in patients taking fluvoxamine. As a result, closer monitoring of anticoagulation status is indicated in these patients. Alprazolam and diazepam are metabolized in part through CYP3A4, and fluvoxamine has been shown to prolong their elimination ([DeVane and Gill 1997](#)). Carbamazepine is partially metabolized through CYP3A4, and elevated carbamazepine levels have been documented in patients concomitantly taking fluvoxamine ([Palmer and Benfield 1994](#)). Other drugs whose metabolism through CYP3A4 may be affected by fluvoxamine include pimozide, methadone, and thioridazine. Also, because of the serious QT interval prolongation that can occur when terfenadine

or astemizole is combined with the potent CYP3A4 inhibitor ketoconazole, it is recommended that fluvoxamine be avoided in patients who require these antihistamines ([DeVane and Gill 1997](#)). Fluvoxamine is contraindicated for use with thioridazine, tizanidine, pimozide, alosetron, ramelteon, and monoamine oxidase inhibitors (MAOIs) ([Jazz Pharmaceuticals 2011](#)).

---

## Use in Pregnancy and Lactation

---

Limited data are available to guide clinicians and patients on the use of fluvoxamine in pregnancy. One study tried to assess teratogenic or perinatal effects relating to fluvoxamine exposure in utero in 92 pregnant women, 37 of whom were taking concomitant medications. No significant difference in adverse events was seen in the treatment group compared with the control group ([Gentile 2005](#)). The FDA lists fluvoxamine in Category C.

Very limited information is available on infants exposed to fluvoxamine during lactation ([Gentile 2005](#)). In the eight cases published, no adverse events were reported.

---

## Conclusion

---

More than three decades of research and clinical experience with fluvoxamine have established it as a generally well-tolerated SSRI with potential efficacy across a broad range of disorders. While millions of patients have taken fluvoxamine and benefited from it worldwide, two factors may have prevented even more widespread use:

drug-drug interactions, which make fluvoxamine a less attractive choice in patients on complex drug regimens; and a perception, especially in the United States, that it is primarily an anti-OCD drug.

## CHAPTER 14

# Citalopram and Escitalopram

Patrick H. Roseboom, Ph.D.

Ned H. Kalin, M.D.

Citalopram (Celexa) and its pharmacologically active enantiomer, escitalopram (Lexapro), are among the most selective serotonin reuptake inhibitors available. Both drugs are widely prescribed and have been shown in large-scale controlled trials to be effective in the treatment of depression; escitalopram has also been shown to be effective in the treatment of anxiety disorders. Generic formulations of both drugs are now available. Both drugs are well tolerated in patients and show a low potential for pharmacokinetic drug-drug interactions. Citalopram and escitalopram have similar effectiveness in the treatment of depression, although some studies suggest a modest superiority of escitalopram over citalopram on some measures of efficacy, including a possibly faster onset of

therapeutic effect for escitalopram. Antagonism of the effects of escitalopram by *R*-citalopram has been invoked to explain the purported therapeutic differences between the two drugs. Also, the affinity of citalopram for histamine receptors appears to reside in the *R*-enantiomer, suggesting that escitalopram has a decreased potential for antihistaminergic side effects. Finally, in terms of cardiac safety, citalopram has a greater potential to prolong the electrocardiogram (ECG) QT interval and produce potentially serious arrhythmias.

---

## History and Discovery

---

The pharmacology of citalopram was first described in 1977 ([Christensen et al. 1977](#); [Hyttel 1977](#)). Citalopram was shown to be a very potent inhibitor of serotonin (5-HT) reuptake in both in vitro and in vivo models ([Hyttel 1977, 1978](#)). It was subsequently discovered that all of the inhibitory activity of citalopram on 5-HT reuptake resides in the *S*-(+)-enantiomer (escitalopram) ([Hyttel et al. 1992](#)). Originally introduced in Denmark in 1989, citalopram was approved by the U.S. Food and Drug Administration (FDA) for the treatment of depression in July 1998. Escitalopram received FDA approval for the treatment of major depressive disorder in August 2002 and for the treatment of generalized anxiety disorder (GAD) in December 2003. Escitalopram also received FDA approval in March 2009 for the treatment of major depressive disorder in adolescents ages 12–17 years.

# Structure-Activity Relations

Citalopram has a single chiral center ([Figure 14-1](#)). A chiral center is an atom surrounded by an asymmetrical arrangement of atoms such that the three-dimensional configuration is not superimposable on its mirror image. At this chiral center, there are two possible stereoisomers. Often, drugs are produced as a mixture of both stereoisomers, referred to as the *racemate*. However, because desired pharmacological activity or unwanted toxicity may reside in only one of the stereoisomers, a stereoisomer-selective formulation may be superior ([Agranat et al. 2002](#)). Citalopram was originally characterized and marketed as the racemate, but subsequently the single stereoisomer of citalopram, escitalopram ([Figure 14-2](#)), was developed for the treatment of depression and other psychiatric disorders. Preclinical studies indicate that inhibition of 5-HT transporter activity resides in the *S*-enantiomer ([Hyttel et al. 1992](#)), with escitalopram being 30 times more potent than *R*-citalopram at inhibiting 5-HT transport ([Owens et al. 2001](#)).

---

**FIGURE 14-1.** Chemical structure of citalopram hydrobromide.

\*Indicates chiral center.

---

**FIGURE 14-2.** Chemical structure of escitalopram oxalate.

A possible explanation for the postulated modest superiority of escitalopram over citalopram in some measures of antidepressant efficacy is provided by the evidence that the *R*-enantiomer of citalopram may interfere with the activity of the *S*-enantiomer, as evidenced in several behavioral and physiological assays (for a review, see [Sánchez 2006](#)). This antagonism has been hypothesized to result from a kinetic interaction at the level of the 5-HT transporter ([Stórustovu et al. 2004](#)).

---

## Pharmacological Profile

---

### Citalopram

Of the selective serotonin reuptake inhibitors (SSRIs) approved to date, citalopram is one of the most selective, with a 524-fold lower potency for inhibiting the human norepinephrine (NE) transporter and a >10,000-fold lower potency for inhibiting the human dopamine transporter (Owens et al. 2001). In addition, citalopram has low affinity for a wide variety of neurotransmitter receptors (for a review, see Hyttel et al. 1995). Citalopram has been reported to have submicromolar affinity for the histamine type 1 (H<sub>1</sub>) receptor (Hyttel 1994; Richelson and Nelson 1984), but this appears to be true only for the *R*-enantiomer (Owens et al. 2001). Citalopram does not show significant inhibition of monoamine oxidase (MAO) (Hyttel 1977). Behavioral studies in rats and mice have shown citalopram to be a potent and selective inhibitor of 5-HT reuptake (Christensen et al. 1977; Hyttel 1994). In contrast, citalopram is ineffective in models that reflect in vivo inhibition of dopamine and NE reuptake (Hyttel 1994). Citalopram is active in various behavioral models related to antidepressant activity (Martin et al. 1990; Sánchez and Meier 1997) and anxiolytic activity (Inoue 1993; Sánchez 1995).

## Escitalopram

Escitalopram is also a highly potent inhibitor of 5-HT reuptake, with a K<sub>i</sub> for binding to the human 5-HT transporter of 1.1 nM compared with a K<sub>i</sub> of 1.9 nM for citalopram and 36 nM for *R*-citalopram (Owens et al. 2001). Escitalopram is the most selective SSRI approved for clinical use, with a 2,600-fold lower potency for inhibiting the human NE transporter and a >45,000-fold lower

potency for inhibiting the human dopamine transporter. Escitalopram has no appreciable binding affinity for a large number of other neurotransmitter receptors ([Owens et al. 2001](#); [Sánchez et al. 2003](#)). Escitalopram shows potent activity in various in vivo paradigms, including a model of 5-HT reuptake inhibition and behavioral models of antidepressant, antiaggressive, and anxiolytic activity (for a review, see [Sánchez et al. 2003](#)). In these in vivo paradigms, escitalopram's potency ranges from being similar to that of citalopram to being approximately twofold greater than that of citalopram. In contrast, in the majority of these paradigms, *R*-citalopram is severalfold less potent than either escitalopram or citalopram.

---

## Pharmacokinetics and Disposition

---

### Citalopram

Citalopram is well absorbed after oral administration, with an absolute bioavailability of 80% for citalopram tablets ([Joffe et al. 1998](#)). The peak plasma concentration is normally observed 2–4 hours following an oral dose ([Kragh-Sørensen et al. 1981](#)). The bioavailability of citalopram is not affected by food ([Baumann 1992](#)), and it is subject to very little first-pass metabolism ([Kragh-Sørensen et al. 1981](#)). The apparent volume of distribution is 12–16 L/kg ([Fredricson Overø 1982](#); [Kragh-Sørensen et al. 1981](#)), which indicates that the drug distributes widely. There is a linear relationship between steady-state plasma

concentration and dose ([Bjerkenstedt et al. 1985](#)), and plasma protein binding is approximately 80% ([Baumann 1992](#)). Systemic clearance of citalopram is 0.3–0.4 L/minute ([Baumann 1992](#)), and renal clearance of citalopram is approximately 0.05–0.08 L/minute ([Sindrup et al. 1993](#)).

Racemic citalopram undergoes *N*-demethylation by the hepatic cytochrome P450 (CYP) system to the major metabolite monodesmethylecitalopram (DCT). CYP enzymes 2C19, 3A4, and 2D6 all contribute approximately equally to the formation of DCT ([Kobayashi et al. 1997](#); [Rochat et al. 1997](#); [von Moltke et al. 1999](#)). DCT also undergoes *N*-demethylation to the minor metabolite didesmylecitalopram (DDCT) by the actions of CYP2D6 ([Sindrup et al. 1993](#); [von Moltke et al. 2001](#)). Clinical studies indicate that the half-lives for citalopram, DCT, and DDCT are approximately 36 hours, 50 hours, and 100 hours, respectively ([Dalgaard and Larsen 1999](#); [Fredricson Overø 1982](#); [Kragh-Sørensen et al. 1981](#)). Citalopram is metabolized by human cytochromes that display genetic polymorphisms, and metabolism of citalopram and DCT is impaired in subjects who show poor metabolism via the CYP2C19 and CYP2D6 pathways ([Baumann et al. 1996](#); [Sindrup et al. 1993](#); [Yu et al. 2003](#)).

## Escitalopram

The clinical pharmacokinetics of escitalopram, reviewed by [Rao \(2007\)](#), are similar to those described for citalopram. The pharmacokinetic characteristics of escitalopram are essentially the same regardless of whether patients are given a single oral dose of 20 mg of escitalopram or 40 mg of racemic citalopram (which contains 20 mg of

escitalopram); this indicates that there is no pharmacokinetic interaction or interconversion between *R*-citalopram and escitalopram ([Rao 2007](#)).

## Mechanism of Action

---

The majority of studies on mechanism of action have focused on citalopram, with a relatively limited number of studies using escitalopram. Because the antidepressant activity of citalopram results from escitalopram, the majority of the conclusions from these studies pertain to both citalopram and escitalopram.

Citalopram is a potent and selective inhibitor of 5-HT reuptake and acts by binding directly to the 5-HT transporter. Citalopram selectively inhibits radioligand binding to the 5-HT transporter ( $K_i=0.75$  nM) versus the NE transporter ( $K_i=3,042$  nM) in rat cortical membranes. A similar selectivity was found for inhibiting the binding of the same radioligands to the cloned human 5-HT and NE transporters expressed in transfected cells and for inhibiting [ $^3$ H]5-HT ( $K_i=8.9$  nM) and [ $^3$ H]NE ( $K_i=30,285$  nM) reuptake into these transfected cells ([Owens et al. 1997](#)).

Several studies have described how repeated dosing alters the effects of citalopram on serotonergic neuronal function. As with other SSRIs, the ability of citalopram to inhibit the firing of 5-HT neurons in the dorsal raphe nucleus is greatly reduced after 14 days of repeated administration ([Chaput et al. 1986](#)). This change is associated with an increase in the ability of citalopram to elevate the extracellular levels of 5-HT in the cortex

([Invernizzi et al. 1994](#)). These two effects appear to result from a desensitization of 5-HT<sub>1A</sub> autoreceptors ([Chaput et al. 1986](#); [Cremers et al. 2000](#); [Invernizzi et al. 1994](#)). This adaptive change of 5-HT<sub>1A</sub> receptors following repeated administration of citalopram, or other SSRIs, has been postulated to underlie the slow onset of antidepressant efficacy that is observed clinically ([Blier and de Montigny 1994](#)).

Evidence suggests that a variety of antidepressants, including those that block monoamine reuptake or metabolism, produce their therapeutic response in part by overcoming depression-associated decreases in neurogenesis and synaptogenesis, possibly through effects on brain-derived neurotrophic factor (BDNF) expression. Citalopram, like several other antidepressants, has been shown to increase the levels of BDNF messenger RNA (mRNA) in various subregions of the rat ventral hippocampus ([Russo-Neustadt et al. 2004](#)) and to induce signaling through the BDNF receptor tyrosine kinase receptor B (TrkB) ([Rantamäki et al. 2007](#)). Interestingly, this effect of antidepressants on TrkB appears to be independent of BDNF release and 5-HT transporter blockade and does not involve a direct binding of the antidepressant to TrkB ([Rantamäki et al. 2011](#)). Escitalopram treatment has been demonstrated to affect circulating BDNF levels. A study in depressed subjects ( $n=18$ ) showed elevated plasma levels of BDNF and decreased platelet levels of BDNF compared with healthy control subjects ( $n=14$ ), and these differences were normalized with 24 weeks of escitalopram (10–40 mg/day) treatment ([Serra-Millàs et al. 2011](#)). Additionally, there are preliminary clinical data suggesting that a polymorphism

within the coding region for BDNF (Val66Met) is associated with therapeutic response to citalopram ([Choi et al. 2006](#)).

A number of studies have implicated the 5-HT<sub>2A</sub> receptor in a variety of neuropsychiatric disorders ([Norton and Owen 2005](#)), and there is evidence implicating the 5-HT<sub>2A</sub> receptor in the mechanism of action of antidepressants, including citalopram ([Chen and Lawrence 2003](#); [Peremans et al. 2005](#)). Also, a large-scale clinical study involving 1,953 patients who participated in the Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) trial identified a significant association between a polymorphism contained in the second intron of the gene for the 5-HT<sub>2A</sub> receptor (rs7997012) and treatment response to citalopram ([McMahon et al. 2006](#)). While perhaps relevant to clinical work, the functional significance of this intronic polymorphism on the 5-HT<sub>2A</sub> receptor has yet to be determined.

Several cellular and in vivo animal model studies have shown that antidepressants can increase glucocorticoid receptor (GR) translocation, induce GR downregulation, and decrease GR agonist-mediated effects ([Anacker et al. 2011](#); [Carvalho and Pariante 2008](#)), and there is evidence suggesting that similar effects occur in vivo in humans. In a double-blind, placebo-controlled, crossover study in healthy men, treatment for 4 days with citalopram 20 mg/day was associated with a diminished ability of cortisol to increase electroencephalogram alpha power and to impair working memory ([Pariante et al. 2012](#)). These results suggest that GR activation by antidepressants does occur in the human brain.

Corticotropin-releasing factor (CRF) mediates many of the effects of psychological stress and is postulated to play a

role in the pathophysiology of depression and anxiety disorders ([Arborelius et al. 1999](#)). In rats, lentiviral-mediated chronic elevation of amygdala CRF reproduces many of the behavioral and endocrine consequences of chronic stress that are consistent with a depressive or anxious phenotype ([Flandreau et al. 2012](#)). Interestingly, chronic escitalopram treatment of these CRF-overexpressing rats for 4 weeks reversed some but not all of the CRF-induced anxiety-like and depressive-like behavioral alterations ([Flandreau et al. 2013](#)).

## Indications and Efficacy

---

### Depression

#### Citalopram

The efficacy of citalopram (dosage range 20–80 mg/day) in the treatment of depression has been shown in at least 11 placebo-controlled clinical trials (for a review, see [Keller 2000](#)). In addition, meta-analyses of multiple placebo-controlled studies reported similar findings ([Bech and Cialdella 1992](#); [Montgomery et al. 1994](#)). In the United States, three large multicenter clinical trials have demonstrated citalopram's efficacy in the treatment of major depression ([Feighner and Overø 1999](#); [Mendels et al. 1999](#); [Stahl 2000](#)). More recently, primary care patients in the United Kingdom were given citalopram 20 mg/day ( $n=274$ ) or the NE reuptake inhibitor reboxetine 4 mg twice daily ( $n=272$ ), which were found to be equally effective in the treatment of severe depression (defined as

scores  $\geq 15$  on the Beck Depression Inventory) ([Wiles et al. 2012](#)).

**STAR\*D trial.** The effectiveness of citalopram has also been demonstrated in a study designed to simulate real-world conditions for the treatment of depression. The STAR\*D trial was a large-scale multicenter study that enrolled 4,041 patients with nonpsychotic major depression in a test of various antidepressant therapies ([Rush et al. 2004](#)). The mean daily dose of citalopram at study exit was 41.8 mg, the remission rates were 28% (when remission was defined as a score of  $\leq 7$  on the 17-item version of the Hamilton Rating Scale for Depression [Ham-D]) and 33% (when defined as a score of  $\leq 5$  on the 16-item Quick Inventory of Depressive Symptomatology, Self-Report [QIDS-SR]), and the response rate was 47% (when response was defined as a  $\geq 50\%$  reduction in QIDS-SR score) ([Trivedi et al. 2006](#)). These response and remission rates are comparable to those found in 8-week controlled clinical trials examining the efficacy of acute antidepressant treatment.

**Long-term treatment with citalopram.** Two placebo-controlled studies indicate that citalopram may be effective in continuation therapy to prevent depression relapse. Both studies showed that for patients with an acute therapeutic response to citalopram, continuation of citalopram therapy at the same dosage (20, 40, or 60 mg/day) for an additional 24 weeks significantly decreased the relapse rate compared with placebo ([Montgomery et al. 1993](#); [Robert and Montgomery 1995](#)). Two additional studies suggest that citalopram may be beneficial in patients with a history of recurrent depression. Long-term

(at least 48 weeks) administration of citalopram at the same fixed dosage at which patients initially showed therapeutic response (20–60 mg/day) can significantly increase the time before depression recurs in adult patients (ages 18–64 years) and in elderly patients (ages 65 years and older) ([Hochstrasser et al. 2001](#); [Klysner et al. 2002](#)).

## **Escitalopram**

A number of placebo-controlled clinical trials and retrospective analyses have demonstrated the efficacy of escitalopram (dosage range 10–20 mg/day) in the treatment of major depression ([Burke et al. 2002](#); [Lepola et al. 2003](#); [Montgomery et al. 2001b](#); [Wade et al. 2002](#)). Also, a large number of retrospective pooled analyses have compared escitalopram with other SSRIs ([Einarson 2004](#); [Kennedy et al. 2006](#); [Llorca et al. 2005](#)). In general, escitalopram was at least as effective as other widely used antidepressants, and in some clinical trials it has been suggested to be superior to other antidepressants based on modestly greater score changes on various depression rating scales, especially in patients with severe depression. In addition, escitalopram has been suggested in a few clinical trials to possibly have a faster onset of therapeutic effect (based on changes in depression rating scale scores), occurring as early as week 1. It remains to be demonstrated whether the modest differences between escitalopram and other antidepressants in controlled clinical trials translate into a therapeutically meaningful difference in the treatment of depression in psychiatric practice.

**Major depressive disorder with severe asthma.** Major depressive disorder is often seen in

asthmatic individuals, and depression may be a risk factor for asthma-related morbidity. In a placebo-controlled, randomized, double-blind proof-of-concept trial ([Brown et al. 2012](#)), escitalopram 10–20 mg/day was evaluated for the treatment of depression in patients ( $n=25$ ) with asthma. Improvement in depression symptoms was seen in both placebo and escitalopram groups from week 1 to study exit at week 12, with a trend favoring escitalopram for depression remission based on changes in the Ham-D score ([Brown et al. 2012](#)).

**Long-term treatment with escitalopram.** In a 36-week placebo-controlled clinical trial, subjects given escitalopram 10–20 mg/day ( $n=181$ ) were less likely to experience relapse following resolution of a depressive episode than were those given placebo ( $n=93$ ) ([Rapaport et al. 2004](#)). Additionally, the effectiveness of long-term escitalopram therapy in the prevention of recurrence of depression was also demonstrated in a group of patients who had been diagnosed with recurrent major depressive disorder ([Kornstein et al. 2006](#)). Patients given escitalopram 10 or 20 mg/day ( $n=73$ ) in this 52-week study had significantly prolonged time to recurrence compared with those given placebo ( $n=66$ ).

**iSPOT-D trial.** Treatment of depression will be significantly improved with the discovery of biomarkers that can identify which patients will respond best to which treatments. For example, depression is associated with impairments in a wide range of cognitive and emotional functioning ([Snyder 2013](#)). The focus of the International Study to Predict Optimized Treatment in Depression (iSPOT-D) trial was to determine whether laboratory

measures of impaired functioning can be used to predict antidepressant treatment outcomes. In one report, medication-free outpatients with nonpsychotic major depression ( $n=665$  completers) were assessed before treatment with 13 computerized tests of cognitive and emotional functioning, and their performance was compared with that of healthy controls ( $n=336$ ). Patients were then randomly assigned to receive 8 weeks of treatment with escitalopram, sertraline, or extended-release venlafaxine ([Etkin et al. 2015](#)). Approximately one-quarter of the patients had significant impairment across most cognitive tests relative to the healthy controls, and these patients had poorer treatment outcomes. For this subset of patients, better task performance predicted remission (based on scores on the 16-item QIDS-SR) with 72% accuracy for treatment with escitalopram but not for treatment with the other antidepressants. Among the patients predicted to be nonresponders, the greatest impairments were on tests of attention, decision speed, working memory, and speed of emotion identification.

Neuroimaging studies have also focused on identifying patterns of brain activation that may be predictive of antidepressant treatment outcomes. Previous functional magnetic resonance imaging (fMRI) studies demonstrated that activation of the right lateral and medial prefrontal cortices and limbic regions during inhibitory responses on the go/no-go task predicted a greater treatment response to escitalopram ([Langenecker et al. 2007](#)). A similar approach was described in a study from the iSPOT-D trial that involved 80 medication-free outpatients with major depression and 34 matched healthy controls ([Gyurak et al. 2016](#)). During the fMRI scans, subjects completed three tasks to assess core domains of cognitive function. Subjects

then received 8 weeks of antidepressant treatment, fMRI scans were repeated, and depression remission was assessed with the Ham-D. Intact activation of the frontoparietal network during inhibitory “no-go” responses predicted remission, particularly for subjects given the SSRIs escitalopram and sertraline. During the “no-go” responses, remitters showed the same pretreatment dorsolateral prefrontal cortex activation as control subjects, and nonremitters showed hypoactivation relative to control subjects. These study findings hold promise for identifying biomarkers that can help predict which patients are most likely to respond to citalopram and escitalopram treatment.

**GENDEP study.** A genome-based approach to identifying genes associated with therapeutic response to escitalopram has also yielded interesting findings. As part of the Genome-Based Therapeutic Drugs for Depression (GENDEP) study, genomewide association analysis examined 539,391 single-nucleotide polymorphisms (SNPs) to identify genes that underlie individual differences in antidepressant treatment response. The partially randomized, single-blind study examined DNA from unrelated patients of European ancestry who were assigned to receive 12 weeks of treatment with either escitalopram 10–30 mg/day ( $n=394$ ) or nortriptyline 50–150 mg/day ( $n=312$ ). Although no marker was associated at a genomewide level of significance, escitalopram response was predicted at a suggestive level of significance ( $P=0.00049$ ) by a synonymous SNP (rs1126757) in the gene for interleukin 11 (*IL11*) ([Uher et al. 2010](#)). In addition, a targeted analysis of 72 a priori selected candidate genes identified an association between escitalopram response and a SNP (rs7801617) in the gene encoding interleukin 6 (*IL6*), a

close homolog of *IL11*. A follow-up epigenetic study examined variations in DNA methylation of *IL11* as a predictor of antidepressant treatment response using a subset of subjects who were randomly selected from the GENDEP study and received either escitalopram ( $n=80$ ) or nortriptyline ( $n=33$ ) ([Powell et al. 2013b](#)). This study found that DNA methylation levels on some CpG islands predicted antidepressant treatment response and that an interaction between CpG island methylation and genotype at rs1126757 could also predict treatment response. These studies are some of the first to provide evidence that a genomic approach may be fruitful for identifying molecular biomarkers that can predict which patients will best respond to specific antidepressants.

Another investigation from the GENDEP study sought to identify gene expression differences present prior to treatment that could predict treatment response. This study examined leukocyte mRNA expression in healthy controls ( $n=34$ ) and depressed patients ( $n=74$ ) before and after 8 weeks of treatment with escitalopram or nortriptyline ([Cattaneo et al. 2013](#)). The analysis was limited to 15 candidate genes that belonged to one of three groups previously implicated in the pathogenesis of depression or putative mechanisms of action of antidepressants (glucocorticoid receptor function, inflammation, and neuroplasticity). In regard to predictors present prior to treatment, nonresponders had higher mRNA levels for interleukin 1 $\beta$  (*IL1 $\beta$* ; +33%), macrophage inhibiting factor (*MIF*; +48%), and tumor necrosis factor (*TNF*; +39%). A similar study using a nonoverlapping set of GENDEP subjects and focusing only on escitalopram treatment also found higher mRNA levels for *TNF* (+20%) in nonresponders ([Powell et al. 2013a](#)).

A second aim of the [Cattaneo et al. \(2013\)](#) study was to identify changes in gene expression occurring during the course of successful treatment that could point to potential targets of drug action. Successful antidepressant treatment was associated with modest reductions in mRNA levels for *IL6* (−9%) and FK506 binding protein 5 (*FKBP5*) (−11%), as well as increases in mRNA levels for *BDNF* (+48%) and VGF nerve growth factor inducible (*VGF*) (+20%). Taken together, these data indicate that the genes thought to serve as predictors of antidepressant response may be separate from the genes hypothesized to be altered by successful treatment. The authors also noted that with the exception of *IL6*, all gene expression differences were in the same direction for both escitalopram and nortriptyline despite their different mechanisms of action, suggesting that these gene expression changes reflect alterations in pathways common to the two antidepressants and not pathways selective to serotonergic or adrenergic neurotransmission ([Cattaneo et al. 2013](#)).

## Depression in Children and Adolescents

Fluoxetine is currently the only FDA-approved medication for the treatment of depression in both children and adolescents (ages 8 years and older). Escitalopram was approved in 2009 for the treatment of depression in adolescents (ages 12-17 years) but not in younger children. In addition, the FDA has mandated the placement of black box warnings on product labels to indicate the potential for increased suicidality associated with the use of SSRIs in patients younger than 25 years. Importantly, a meta-

analysis of pediatric trials conducted between 1988 and 2006 indicated that the benefits of antidepressant treatment of the young outweigh the risks ([Bridge et al. 2007](#)).

## **Citalopram**

Only a limited number of clinical studies have examined the effectiveness of citalopram in the treatment of depression in youth. In one double-blind trial involving 174 children and adolescents (ages 7–17 years), citalopram (20 mg/day) showed a modest superiority over placebo in the treatment of depression ([Wagner et al. 2004](#)). Conversely, citalopram (10–40 mg/day) was not superior to placebo in a clinical trial involving 244 adolescents (ages 13–18 years) receiving treatment for 12 weeks ([von Knorring et al. 2006](#)). Clearly, additional clinical trials are required to establish the efficacy and safety of citalopram in the treatment of childhood depression.

## **Escitalopram**

Three studies have addressed the effectiveness of escitalopram in the pediatric population. Escitalopram was shown to be effective in the treatment of depression in adolescents (ages 12–17 years) in a randomized, double-blind, placebo-controlled multicenter clinical trial ([Emslie et al. 2009](#)). In this study, the group given escitalopram 10–20 mg/day ( $n=155$ ), compared with the group given placebo ( $n=157$ ), had greater improvement based on change from baseline to week 8 in scores on the Children's Depression Rating Scale—Revised (CDRS-R). In another randomized, double-blind trial investigating treatment of major depressive disorder in children and adolescents (ages 6–17

years), those given escitalopram 10–20 mg/day ( $n=131$ ) did not improve significantly more than those given placebo ( $n=133$ ). However, in a post hoc analysis of just the adolescents (ages 12–17 years), those given escitalopram ( $n=80$ ), compared with those given placebo ( $n=77$ ), had significantly improved CDRS-R scores from baseline to week 8 ([Wagner et al. 2006](#)). Finally, the long-term benefits of escitalopram treatment for depression in adolescents were demonstrated in an extension trial that enrolled a subset of the sample participating in the aforementioned [Emslie et al. \(2009\)](#) study. This double-blind 16- to 24-week trial ([Findling et al. 2013](#)) showed that in comparison with subjects given placebo ( $n=40$ ), those given escitalopram 10–20 mg/day ( $n=37$ ) had a modest but statistically significantly greater improvement in CDRS-R score from baseline of the lead-in study to treatment week 24 (8-week lead-in study plus 16-week extension) ( $P=0.005$ ).

## Generalized Anxiety Disorder

### Citalopram

No large-scale randomized, double-blind clinical trials have examined the effectiveness of citalopram in the treatment of GAD. As described in the next subsection, all large-scale trials have focused on the use of escitalopram in the treatment of GAD.

### Escitalopram

The efficacy of escitalopram in the treatment of GAD has been established in several randomized controlled clinical trials ([Baldwin and Nair 2005](#)). Escitalopram's effectiveness

in acute treatment of GAD was shown in three double-blind, placebo-controlled clinical trials that were also subjected to pooled analysis. These studies demonstrated that escitalopram (10–20 mg/day administered for 8–12 weeks) was superior to placebo ([Davidson et al. 2004](#); [Goodman et al. 2005](#); [Stein et al. 2005](#)). The efficacy of escitalopram (10–20 mg/day) in the long-term treatment of GAD was demonstrated in two 24-week controlled clinical trials, one open label ([Davidson et al. 2005](#)) and the other double blind ([Bielski et al. 2005](#)). Escitalopram also showed efficacy in the prevention of GAD relapse for an additional 24–76 weeks ([Allgulander et al. 2006](#)).

## Panic Disorder

### Citalopram

Few well-controlled studies have evaluated the effectiveness of citalopram in the treatment of panic disorder. In a 1-year placebo-controlled, double-blind study of 279 patients who agreed to continue treatment after an acute treatment period during which they had been randomly assigned to receive citalopram (20 or 30 mg/day, or 40 or 60 mg/day), clomipramine (60 or 90 mg/day), or placebo, all drug-treated groups showed significantly greater improvement compared with placebo on a variety of anxiety rating instruments, including the Clinical Anxiety Scale (CAS) panic attack item. The authors concluded that citalopram at a dosage range of 20–60 mg/day was an effective long-term therapy for the management of panic disorder ([Lepola et al. 1998](#)).

### Escitalopram

Escitalopram 5–10 mg/day was shown to be effective in the treatment of panic disorder in a 10-week randomized, double-blind, placebo-controlled, flexible-dosage study in patients with a diagnosis of panic disorder with or without agoraphobia ([Stahl et al. 2003](#)). The relative panic attack frequency was significantly lower in the escitalopram group ( $n=125$ ) than in the placebo group ( $n=114$ ), and at the end of the study, a greater proportion of patients had zero panic attacks in the escitalopram group (50%) than in the placebo group (38%) ( $P=0.051$ ).

## Social Anxiety Disorder (Social Phobia)

### Citalopram

A large-scale, double-blind, placebo-controlled study demonstrated that paroxetine is effective in the treatment of social anxiety disorder, suggesting that some SSRIs may be effective in the treatment of this disorder ([Stein et al. 1998](#)). Despite the lack of large-scale, placebo-controlled studies using citalopram, case reports indicate that citalopram may have effectiveness in the treatment of social anxiety disorder ([Bouwer and Stein 1998](#); [Lepola et al. 1994, 1996](#); [Simon et al. 2001](#)). In addition, one 12-week small-scale ( $n=21$ ), flexible-dose, open-label study demonstrated the effectiveness of citalopram (20–60 mg/day) in relieving the symptoms of social anxiety disorder in patients with comorbid depression ([Schneier et al. 2003](#)).

### Escitalopram

Two large-scale, multinational, multicenter clinical trials have demonstrated the effectiveness of escitalopram in the treatment of social anxiety disorder. In a 24-week fixed-dosage trial in patients with a diagnosis of social anxiety disorder, escitalopram at three dosages—5 mg/day ( $n=167$ ), 10 mg/day ( $n=167$ ), or 20 mg/day ( $n=170$ )—and paroxetine 20 mg/day ( $n=169$ ) each showed a statistically superior therapeutic effect compared with placebo ( $n=166$ ) by week 12 ([Lader et al. 2004](#)). Further improvement was seen by week 24 for all dosages of escitalopram and for paroxetine, and escitalopram 20 mg/day was superior to paroxetine 20 mg/day. In a 12-week study, escitalopram 10–20 mg/day ( $n=181$ ) produced a superior therapeutic response compared with placebo ( $n=177$ ) based on mean change from baseline in the Liebowitz Social Anxiety Scale score ([Kasper et al. 2005](#)). In a long-term study, escitalopram treatment at dosages of 10 or 20 mg/day for up to 24 weeks was shown to be effective in preventing relapse of social anxiety disorder following successful short-term therapy, with relapse being 2.8 times more likely with placebo treatment ( $n=181$ ) than with escitalopram treatment ( $n=190$ ) ([Montgomery et al. 2005](#)).

## Anxiety Associated With Major Depressive Disorder

### Citalopram

A retrospective study of 2,000 depressed patients enrolled in eight double-blind, placebo-controlled clinical trials revealed that citalopram was effective in relieving the symptoms of anxiety in depressed patients based on a

greater decrease in the anxiety factor of the Ham-D ([Flicker et al. 1998](#)). Another double-blind, placebo-controlled study in 323 patients with a diagnosis of major depression revealed a significant antianxiety effect of citalopram 20–60 mg/day compared with placebo based on decreases in the Hamilton Anxiety Scale (Ham-A) score ([Stahl 2000](#)).

## **Escitalopram**

The effectiveness of escitalopram in the treatment of anxiety symptoms associated with major depressive disorder was evaluated in a pooled analysis of five clinical trials ([Bandelow et al. 2007](#)). These placebo-controlled trials were originally designed to examine the effectiveness of escitalopram in treating major depression. In the pooled analysis, escitalopram 10–20 mg/day ( $n=850$ ) was consistently superior to placebo ( $n=737$ ) in relieving the anxious symptoms associated with depression, as evaluated with several different assessments of anxiousness. The analyses presented in this pooled study indicate that escitalopram is effective in relieving anxiety symptoms in depressed patients.

# **Obsessive-Compulsive Disorder**

## **Citalopram**

To date, a limited number of clinical studies have evaluated the effectiveness of citalopram in the treatment of obsessive-compulsive disorder (OCD). In the only published large-scale ( $N=401$ ) double-blind, placebo-controlled study of citalopram in the treatment of OCD, all three dosages of citalopram (20, 40, and 60 mg/day) given for 12 weeks

were significantly more effective than placebo in relieving the symptoms of OCD ([Montgomery et al. 2001a](#)). Citalopram appears to be effective in treating both obsessions and compulsions.

## **Escitalopram**

The effectiveness of escitalopram in the treatment of OCD was demonstrated in a 24-week double-blind, placebo-controlled multicenter clinical trial ([Stein et al. 2007](#)). In this study, escitalopram 20 mg/day ( $n=116$ ) and paroxetine 40 mg/day ( $n=119$ ) produced significant improvement compared with placebo, and by week 24, all treatments, including escitalopram at 10 mg/day ( $n=116$ ), were superior to placebo ( $n=115$ ). Long-term treatment with escitalopram was shown in one large-scale study to prevent relapse of OCD in patients who had responded to initial treatment ([Fineberg et al. 2007](#)). Patients treated with escitalopram 10 or 20 mg/day ( $n=163$ ) showed a significantly greater time to relapse compared with those receiving placebo ( $n=157$ ).

## **Investigational Uses**

---

### **Stress-Induced Myocardial Ischemia**

#### **Escitalopram**

Substantial evidence implicates emotional stress as a trigger of acute coronary syndromes, and this effect can be reproduced in laboratory settings; studies show that up to 70% of patients with stable coronary heart disease display

mental stress-induced myocardial ischemia (MSIMI) ([Strike and Steptoe 2003](#)). The Responses of Mental Stress Induced Myocardial Ischemia to Escitalopram Treatment (REMIT) study was designed to determine whether SSRI treatment could improve heart function following mental stress in patients with laboratory-diagnosed MSIMI. At the end of this 6-week randomized, double-blind, placebo-controlled study, significantly more of the patients receiving escitalopram treatment ( $n=56$ ; 5 mg/day titrated to 20 mg/day over 3 weeks) than of those receiving placebo ( $n=56$ ) (odds ratio, 2.62 [95% confidence interval, 1.06–6.44];  $P=0.04$ ) showed no MSIMI during three mental stressor tasks ([Jiang et al. 2013](#)). There was no statistically significant effect for exercise-induced ischemia. These results offer a preliminary indication of the potential utility of SSRIs in preventing mental stress-induced acute coronary syndromes.

## Alzheimer's Disease

### Citalopram

Brain accumulation of amyloid plaques formed by the aggregation of the amyloid- $\beta$  peptide ( $A\beta$ ) is thought to be central to the pathophysiology of Alzheimer's disease (AD) ([Holtzman et al. 2011](#)). The aggregation of  $A\beta$  into plaques is concentration dependent ([Bero et al. 2011](#); [Lomakin et al. 1997](#)); therefore, methods to decrease  $A\beta$  levels may be therapeutic. Previous studies have shown that serotonin signaling suppresses the generation of  $A\beta$  in vitro and in animal models of AD ([Cirrito et al. 2011](#); [Nitsch et al. 1996](#)). In an aged transgenic AD mouse model (APP/PS1 plaque-bearing mice), acute citalopram treatment led to a dose-

dependent decrease in brain interstitial fluid A $\beta$  levels, and chronic citalopram treatment arrested the growth of preexisting plaques and reduced the appearance of new plaques by 78% ([Sheline et al. 2014](#)). In addition, in a double-blind study, acute administration of citalopram (60 mg/day) in 23 healthy humans (ages 18–50 years, 11 females) resulted in lower cerebrospinal fluid A $\beta$  production (37%) and concentration (38%) compared with placebo ([Sheline et al. 2014](#)). To the extent that AD involves the accumulation of A $\beta$ , these results suggest a potential role for SSRI treatment in the prevention of AD, and future studies should be aimed at defining the mechanism by which citalopram treatment lowers A $\beta$  levels.

## Side Effects and Toxicology

### Citalopram

In a meta-analysis of 746 depressed patients involved in several short-term clinical trials, the most common adverse events associated with citalopram were nausea and vomiting (20%), increased sweating (18%), and dry mouth and headache (17%) ([Baldwin and Johnson 1995](#)). Analysis of an integrated safety database, which includes data from 3,107 patients enrolled in 24 clinical trials, indicated that in placebo-controlled trials, nausea, dry mouth, somnolence, increased sweating, tremor, diarrhea, and ejaculatory failure of mild to moderate severity occurred with significantly greater frequency in patients given citalopram than in those given placebo ([Muldoon 1996](#)). The incidences of these adverse events with citalopram were less than 10%

above those seen with placebo and were comparable to those reported with other SSRIs. Citalopram had a tolerability that was superior to that of the tricyclic antidepressants, with the exception that nausea and ejaculatory failure occurred with a 5% greater frequency in patients given citalopram ([Keller 2000](#)).

## Escitalopram

In general, the side effects associated with escitalopram are similar to those observed with citalopram. In three placebo-controlled clinical trials performed with escitalopram, rates of discontinuation due to adverse events did not differ for patients given a dosage of 10 mg/day versus patients in the placebo group ([Burke et al. 2002](#); [Montgomery et al. 2001b](#); [Wade et al. 2002](#)). In the trial that included an escitalopram dosage of 20 mg/day, the rate of discontinuation was 10.4% for the group given escitalopram versus 2.5% for the group given placebo ([Burke et al. 2002](#)). In addition, the rate of adverse events overall in the group receiving escitalopram 20 mg/day (85.6%) was significantly greater than the rate in the placebo group (70.5%). Regardless of dosage, the adverse events that have been reported to occur more frequently with escitalopram compared with placebo are nausea, diarrhea, insomnia, dry mouth, and ejaculatory disorder, with nausea being reported most frequently, at a rate of 15% ([McRae 2002](#)). No published studies have reported clinically significant findings in laboratory test values, vital signs, weight gain or loss, or ECG values.

# Specific Effects and Syndromes

## QT Interval Prolongation

Citalopram has been shown to be associated with a dose-dependent prolongation of the corrected QT (QTc) interval in the ECG, which can increase the risk of a potentially fatal abnormal heart rhythm called torsades de pointes. As a result, the FDA recommends that citalopram not be prescribed at dosages greater than 40 mg/day ([The Medical Letter on Drugs and Therapeutics 2013](#); [U.S. Food and Drug Administration 2013](#)). In addition, citalopram use should be avoided in populations at increased risk of QTc interval prolongation, such as patients with congenital long QT syndrome. For at-risk patients for whom no satisfactory alternatives to citalopram are available, a low dosage of citalopram should be used, and ECG and/or electrolytes should be monitored. Citalopram should be discontinued in patients with a QTc interval greater than 500 msec. Finally, for patients older than 60 years, dosages greater than 20 mg/day are not recommended. As in any clinical situation, the clinician must weigh the risk-benefit ratio for the treatment, and in some cases it may be reasonable to use dosages that exceed the FDA guidelines. Importantly, escitalopram at dosages therapeutically equivalent to those of citalopram has not been demonstrated to significantly impact the QTc interval.

## Hyponatremia

Citalopram and escitalopram have been shown to produce hyponatremia in case reports involving elderly patients, and this information has been reviewed elsewhere ([Jacob and Spinler 2006](#)). In addition to advanced age, other factors

that may increase the likelihood of hyponatremia include female gender, concurrent diuretic use, low body weight, and recent pneumonia. Treatment of SSRI-induced hyponatremia usually involves fluid restriction and/or administration of a loop diuretic such as furosemide and may include discontinuation of the SSRI.

## **Discontinuation Syndrome**

The abrupt cessation of antidepressant therapy can result in a discontinuation syndrome characterized by dizziness, nausea and vomiting, lethargy, and flu-like symptoms. This syndrome is more common with short-half-life SSRIs such as paroxetine and less common with long-half-life SSRIs such as fluoxetine. The data obtained from clinical trials suggest that the adverse events associated with discontinuation of citalopram or escitalopram tend to be mild and transient ([Baldwin et al. 2007](#); [Markowitz et al. 2000](#); [Montgomery et al. 1993](#)). Dose tapering is recommended for patients discontinuing treatment.

## **Treatment-Emergent Suicidal Ideation and Suicide**

Considerable attention has been focused in recent years on the possibility that antidepressant drugs, especially SSRIs, may lead to treatment-emergent suicidal ideation (TESI) and an increased risk of suicide in some patients, particularly at the onset of therapy ([Jick et al. 2004](#)). This issue is of great concern in young patients and was described earlier in the chapter (see earlier section “Depression in Children and Adolescents”). In the case of citalopram, analyses of data obtained from 17 controlled clinical trials involving 5,000 patients indicate that the

group of patients receiving citalopram had the lowest rate of suicide compared with the groups receiving placebo, tricyclic antidepressants, or other SSRIs ([Nemeroff 2003](#)). The risk of suicide associated with escitalopram was evaluated from data contained in the Summary Basis of Approval reports obtained from the FDA ([Khan and Schwartz 2007](#)). This study did not detect a significantly greater rate of suicide in the escitalopram group compared with either the citalopram or the placebo group. A meta-analysis of the escitalopram clinical trials database—consisting of 2,277 escitalopram-treated patients and 1,814 placebo-treated patients—also yielded no indication that escitalopram increased suicidal behavior in major depressive disorder and anxiety disorders ([Pedersen 2005](#)).

Although the data do not indicate a significantly greater risk of suicide for patients receiving either citalopram or escitalopram compared with those receiving placebo, most antidepressant studies show that a limited number of patients will exhibit TESI on initiation of therapy. Family and twin studies provide some evidence of a genetic influence on suicidal behavior, and it has been postulated that TESI may also be genetically influenced. Interestingly, a study in patients participating in the STAR\*D trial demonstrated a significant association between citalopram-induced TESI in men and polymorphisms near the gene encoding the transcription factor cyclic adenosine monophosphate (cAMP) response-element binding (*CREB*) protein ([Perlis et al. 2007](#)). This protein is of great interest because it mediates the effects of second messengers on new gene transcription and has been implicated in antidepressant action and suicide ([Dowlathshahi et al. 1998](#); [Dwivedi et al. 2003a](#)). An analysis of nine candidate genes in patients from the GENDEP study who received either

escitalopram or nortriptyline identified polymorphisms in *BDNF* as being associated with TESI, and there was also a significant interaction between variants in *BDNF* and *TRKB*, the gene encoding the BDNF receptor (Perroud et al. 2009). A proposed role for the BDNF pathway in TESI is consistent with previous reports of lower levels of BDNF mRNA and protein in the hippocampus and prefrontal cortex of suicide victims and lower levels of BDNF protein in the plasma of suicide attempters (Dwivedi et al. 2003b; Karege et al. 2005; Kim et al. 2007). In addition, CREB is thought to control *BDNF* gene transcription, providing a functional link between these two genetic associations and TESI (Dwivedi et al. 2003a; Finkbeiner 2000).

Finally, in a genomewide association study also using subjects from the GENDEP study, the strongest association with TESI was with a single-nucleotide polymorphism located 30 kilobytes downstream of the gene encoding guanine deaminase (*GDA*). This study also found two suggestive escitalopram-specific associations with TESI that were contained in the gene for Kv channel-interacting protein 4 (*KCNIP4*) and near the gene for elongation protein 3 homolog (*ELP3*) (Perroud et al. 2012). Although no definitive conclusions can be drawn from this study or other genetic studies until they are replicated with larger samples, the findings point to the possibility that in the future, genetic markers may be used to predict not only treatment response but also vulnerabilities to the adverse effects of specific drugs.

---

## Drug-Drug Interactions

---

Even though the majority of a dose of citalopram is metabolized in the liver (75%), because multiple P450 enzymes (CYP2C19, CYP3A4, and CYP2D6) contribute equally to the metabolism of citalopram and escitalopram, inhibition of any one of these enzymes by another drug is unlikely to significantly impact the overall metabolism of citalopram or escitalopram. Consistent with this, there are relatively few reports in the literature of drug-drug interactions involving citalopram or escitalopram. Because of the possibility of a potentially fatal pharmacodynamic interaction resulting in the serotonin syndrome, neither citalopram nor escitalopram should be administered with an MAO inhibitor or within 14 days of discontinuing an MAO inhibitor.

---

## Conclusion

---

Citalopram and escitalopram are highly selective 5-HT reuptake inhibitors that are well tolerated and effective for the treatment of depression, with escitalopram also having proven efficacy in large-scale clinical trials in the treatment of GAD. Although the use of citalopram and escitalopram in the treatment of other psychiatric conditions has not been as thoroughly studied, the few well-controlled trials that have been completed suggest that both drugs may have a significant role in treating a wide range of psychiatric illnesses, including panic disorder, social anxiety disorder, anxiety associated with depression, and OCD. An advantage of citalopram and escitalopram compared with some other common SSRIs is a relatively weak inhibition of liver CYP450 enzymes, which reduces the potential for adverse

pharmacokinetic drug-drug interactions. In addition, because escitalopram does not share with citalopram a modest affinity for the histamine H<sub>1</sub> receptor, it may have a lower potential for antihistaminergic side effects compared with citalopram, a difference that has yet to be demonstrated in a clinical trial. In terms of effects on cardiac function, escitalopram's risk of producing QT interval prolongation appears to be lower than that of citalopram, and careful monitoring must accompany use of citalopram in patients at risk for QT prolongation. There are a number of clinical trials comparing escitalopram with a variety of other antidepressants, including citalopram and venlafaxine, that suggest that escitalopram may have a faster onset of antidepressant efficacy and modest superiority in the treatment of individuals who are severely depressed. However, a clinically significant superiority of escitalopram over citalopram in the "real world" of psychiatric practice remains to be definitely established.

## CHAPTER 15

# **Trazodone and Nefazodone**

Robert N. Golden, M.D.

Karon Dawkins, M.D.

Linda Nicholas, M.D.

**Trazodone** was among the earliest “second generation” antidepressants to become available for clinical use in the United States in the early 1980s. Its side-effect profile and potential toxicity were considerably different from—and in many instances preferable to—those of the original antidepressants (i.e., the monoamine oxidase inhibitors [MAOIs] and tricyclic antidepressants [TCAs]). Several years later, trazodone’s pharmacological “cousin,” nefazodone, also became available.

---

## **Trazodone**

---

# History and Discovery

Trazodone was first synthesized in Italy about four decades ago, and clinical studies began in the United States in 1978. In sharp contrast to most other antidepressants available at the time, trazodone showed minimal effects on muscarinic cholinergic receptors.

In 1982, trazodone was introduced for clinical use in the United States under the brand name Desyrel. The medication is now available in generic formulation and also in an extended-release preparation (Oleptro).

## Pharmacological Profile

Trazodone is a relatively weak SSRI; however, it is relatively *specific* for serotonin (5-HT) uptake inhibition, with minimal effects on norepinephrine (NE) or dopamine reuptake (Hyttel 1982) (Figure 15-1). Trazodone appears to increase extracellular 5-HT concentrations through a combination of mechanisms involving the 5-HT transporter (5-HTT) and the serotonin<sub>2A/2C</sub> (5-HT<sub>2A/2C</sub>) receptors (Pazzagli et al. 1999). In addition, trazodone has some 5-HT receptor antagonist activity (Haria et al. 1994). Its active metabolite, *m*-chlorophenylpiperazine (mCPP), is a potent direct 5-HT receptor agonist. Thus, trazodone can be viewed as a mixed serotonergic agonist-antagonist, with the relative amount of mCPP accumulation affecting the relative degree of the predominant agonist activity. Sustained administration is associated with enhanced serotonergic neurotransmission in vivo in the rat brain (Ghanbari et al. 2010).

---

**FIGURE 15-1.** Chemical structure of trazodone.

In vivo, trazodone is virtually devoid of anticholinergic activity, and in clinical studies, the incidence of anticholinergic side effects is similar to that seen with placebo. Trazodone is a relatively potent antagonist of postsynaptic  $\alpha_1$ -adrenergic receptors, and it has a propensity to cause orthostatic hypotension. Trazodone has moderate antihistaminergic (histamine<sub>1</sub> [H<sub>1</sub>] receptor) activity.

## Pharmacokinetics and Disposition

Trazodone is well absorbed after oral administration, with peak blood levels occurring about 1-2 hours after dosing. Trazodone is 89%-95% bound to plasma protein. Elimination appears to be biphasic; the initial alpha and subsequent beta phases have half-lives of 3-6 and 5-9 hours, respectively. Bioavailability is not influenced by age or food intake.

Trazodone undergoes extensive hepatic metabolism. The active metabolite mCPP is cleared more slowly than the parent compound (4- to 14-hour half-life) and reaches higher concentrations in the brain than in plasma ([Caccia et](#)

[al. 1981](#)). The cytochrome P450 (CYP) 2D6 and 3A microsomal enzyme systems also appear to play a role in trazodone metabolism. The relation between steady-state blood levels and clinical response to trazodone is not well defined.

## Mechanism of Action

The ultimate mechanism of action of trazodone remains unclear. Although the drug is described as a 5-HT reuptake inhibitor, its effects on this neurotransmitter system are complex. Trazodone has relative selectivity for 5-HT reuptake sites ([Hyttel 1982](#)); however, in vivo, it blocks the head twitch response induced by classic 5-HT agonists in animals. The potent 5-HT receptor agonist properties of trazodone's major metabolite, mCPP, may play a role in the mechanism of action of the parent compound. Trazodone, unlike the vast majority of antidepressants, does not produce downregulation of  $\beta$ -adrenergic receptors in rat cortex ([Sulser 1983](#)).

## Indications and Efficacy

The primary indication for trazodone is treatment of major depressive disorder. Early reviews found that trazodone's antidepressive efficacy was similar to that of the TCAs and the tetracyclic mianserin ([Lader 1987](#); [Schatzberg \(1987\)](#)).

Questions have been raised about the effectiveness of trazodone in treating severely ill depressed patients, especially those with prominent psychomotor retardation. [Shopsin et al. \(1981\)](#) pointed out that in several

unpublished double-blind, controlled studies, the rates of clinical response to trazodone were low (i.e., 10%–20%).

The performance of trazodone, in direct comparisons with other second-generation antidepressants, has been mixed. In a double-blind, placebo-controlled comparison with venlafaxine, the final response rates were 55% for placebo, 60% for trazodone, and 72% for venlafaxine. Trazodone was more effective than venlafaxine in ameliorating sleep disturbances and was associated with the most dizziness and somnolence ([Cunningham et al. 1994](#)). In a double-blind comparison with bupropion, response rates were 46% for trazodone and 58% for bupropion ([Weisler et al. 1994](#)). In a double-blind study of 200 hospitalized patients experiencing a moderate to severe major depressive episode, mirtazapine yielded greater reductions in depression ratings than did trazodone ([van Moffaert et al. 1995](#)).

Three double-blind studies reported that trazodone had antidepressant efficacy similar to that of other antidepressants in geriatric patients ([Gerner 1987](#)). However, trazodone's association with orthostatic hypotension may increase the risk of falls, with devastating consequences in elderly patients. Still, trazodone is often helpful for geriatric patients with depression who have severe agitation and insomnia. A survey of British geropsychiatrists identified trazodone as one of their most popular adjuncts or alternatives to atypical antipsychotics in the management of behavioral symptoms in the elderly ([Condren and Cooney 2001](#)). A Cochrane Database review found insufficient evidence to support trazodone as a treatment for the behavioral and psychological symptoms of dementia, although the review could not conclude that trazodone was ineffective, given the limited number of

eligible studies ([Martinon-Torres et al. 2004](#)). A recent study of 30 patients with Alzheimer's disease found that trazodone produced a normalization of circadian rhythms, which are often disturbed in this patient population ([Grippe et al. 2015](#))

In a randomized, double-blind, placebo-controlled trial, the anxiolytic efficacy of trazodone was comparable to that of diazepam in weeks 3–8 of treatment for generalized anxiety disorder, although patients treated with diazepam had greater improvement during the first 2 weeks of treatment ([Rickels et al. 1993](#)).

Many clinicians use low-dose trazodone as an alternative to benzodiazepines for the treatment of insomnia. Trazodone is the second most prescribed agent for primary insomnia, even though there is minimal evidence to support its use for this indication ([Mendelson 2005](#); [Rosenberg 2006](#)). Controlled trials have confirmed trazodone's efficacy (at doses of 50–100 mg) in treating antidepressant-associated insomnia ([Nierenberg et al. 1994](#)). A retrospective analysis at a Department of Veterans Affairs (VA) medical center found that approximately 24% of patients receiving trazodone were taking other primary antidepressants ([Clark and Alexander 2000](#)). Another VA study of patients with posttraumatic stress disorder (PTSD) found that of those patients who were able to tolerate trazodone (60 of 72 patients), 92% reported that it improved sleep onset and 78% reported that it improved sleep maintenance ([Warner et al. 2001](#)). A recent study found that trazodone improved the Apnea-Hypopnea Index in patients with obstructive sleep apnea (OSA) without any deleterious effects on oxygen saturation or non-rapid eye movement (REM) arousal threshold, suggesting that the

drug might have potential as a treatment for OSA ([Smales et al. 2015](#)).

Trazodone is more effective than placebo when added to antipsychotic medication in the treatment of the negative symptoms of schizophrenia ([Singh et al. 2010](#); [Watanabe 2011](#)). A double-blind, placebo-controlled trial found trazodone to be effective in treating antipsychotic-induced akathisia ([Stryjer et al. 2010](#)).

A recent review highlighted the common off-label use of trazodone in a number of conditions, including bulimia, fibromyalgia, chronic pain, and diabetic neuropathy ([Bossini et al. 2015](#)). We agree with the authors' conclusion that large randomized controlled trials are needed to determine whether there is adequate scientific evidence to support trazodone's use for any of these indications.

Trazodone should be initiated at a low dose and increased gradually, based on clinical response and tolerance to side effects. For the treatment of a major depressive episode, the suggested initial dosage is 150 mg/day, with increases of 50-mg increments every 3–4 days. Doses may be divided, although many patients prefer bedtime dosing because of the sedating effects. The maximum dosage recommended for outpatients is 400 mg/day, although for inpatients with more severe depression, dosages up to 600 mg/day have been used. When trazodone is prescribed as a hypnotic agent, the usual dose is 50 mg at bedtime, although some patients may require as little as 25 mg or as much as 200–300 mg.

## Side Effects and Toxicology

Because of its lack of anticholinergic side effects, trazodone is especially useful for patients with prostatic hypertrophy, closed-angle glaucoma, or severe constipation. Trazodone's propensity to cause sedation is a dual-edged sword. For many patients, the relief from agitation, anxiety, and insomnia can be rapid; for others, including those with psychomotor retardation and low energy, trazodone may not be tolerable.

Trazodone was found to be among the top three medications associated with orthostatic hypotension in patients attending a VA geriatric clinic ([Poon and Braun 2005](#)). More than 200 cases of trazodone-associated priapism have been reported ([Thompson et al. 1990](#)), and the manufacturer estimates that the incidence of any abnormal erectile function is approximately 1 in 6,000 male patients. The risk appears to be greatest during the first month of treatment at low dosages (<150 mg/day). Early recognition of any abnormal erectile function is important and should prompt immediate discontinuation of trazodone treatment.

In overdose situations, trazodone appears to be *relatively* safer than TCAs, MAOIs, and a few of the other second-generation antidepressants, especially when it is the only agent taken. Fatalities are rare, and uneventful recoveries have been reported after ingestion of doses as high as 6,000–9,200 mg ([Ayd 1984](#)). When trazodone overdoses occur, clinicians should carefully monitor for hypotension.

In common with several other sedative-hypnotics, trazodone has the potential to impair driving skills, especially in new users, who have been shown to have an increased risk of motor vehicle crashes. The risk estimate for trazodone is roughly comparable to that of blood alcohol concentration levels of 0.09% ([Hansen et al. 2015](#)).

# Drug-Drug Interactions

Trazodone can potentiate the effects of other central nervous system (CNS) depressants. Patients should be warned about increased drowsiness and sedation when trazodone is combined with other CNS depressants, including alcohol.

The combination of trazodone with an MAOI, as with other antidepressants, should be handled with great caution, although there are case reports of the successful combination of trazodone with an MAOI. Development of the serotonin syndrome has been associated with the combination of trazodone with other proserotonergic agents. Trazodone inhibits the antihypertensive effects of clonidine. Trazodone can cause hypotension, especially orthostatic hypotension, and concomitant administration of trazodone with antihypertensive therapy may require a reduction in the dose of the antihypertensive agent.

Clinically significant cases of suspected trazodone-warfarin interactions have been described.

## Nefazodone

---

### History and Discovery

Trazodone's sedative properties and association with orthostatic hypotension inspired an effort to discover a modified molecule that would possess a more desirable pharmacological profile. This led to the development of nefazodone ([Figure 15-2](#)), which became available in the

United States in 1994. Nefazodone and trazodone share a common active metabolite.

**FIGURE 15-2.** Chemical structure of nefazodone.

In 2004, the manufacturer of Serzone (nefazodone) announced that it was discontinuing the drug's sale in the United States, citing declining sales. The drug had been banned in many countries because of its association with liver toxicity, and lawsuits against that manufacturer and the FDA had been initiated in this country. Nefazodone continues to be available in the United States as a generic medication.

## Pharmacological Profile

Nefazodone is a 5-HT<sub>2</sub> receptor antagonist and a weak inhibitor of 5-HT and NE reuptake ([Figure 15-2](#)). It has little affinity for  $\alpha_2$ -adrenergic,  $\beta$ -adrenergic, or serotonin<sub>1A</sub> (5-HT<sub>1A</sub>) receptors, and its affinity for the  $\alpha_1$ -adrenergic receptor is less than that of trazodone. Nefazodone is inactive at most other receptor-binding sites ([Taylor et al. 1986](#)).

Nefazodone demonstrates several of the classic preclinical characteristics of antidepressants. In humans,

nefazodone does not suppress REM sleep, in contrast to most other antidepressants ([Sharpley et al. 1996](#)).

## Pharmacokinetics and Disposition

Nefazodone is rapidly and completely absorbed and is then extensively metabolized, resulting in a low (about 20%) and variable absolute bioavailability. The plasma half-life is only 2–4 hours. Nefazodone has three active metabolites: triazole dione, hydroxynefazodone, and mCPP. Triazole dione is a specific 5-HT<sub>2</sub> receptor antagonist with weaker affinity for that receptor than the parent compound and no appreciable effects on 5-HT reuptake. With a plasma half-life of 18 hours, triazole dione predominates in the plasma, occurring at concentrations approaching four times that of the parent compound. Hydroxynefazodone has affinities for the 5-HT<sub>2</sub> receptor and 5-HT reuptake site that are similar to those of the parent compound. Its plasma half-life is between 1.5 and 4 hours, and at steady state, plasma concentrations are approximately 40% of those of the parent compound. mCPP is a direct agonist at the 5-HT<sub>1</sub>, 5-HT<sub>2</sub>, and serotonin<sub>3</sub> (5-HT<sub>3</sub>) receptors, with one order of magnitude higher affinity for 5-HT<sub>2C</sub> receptors. mCPP has a plasma half-life of 4–8 hours, and its plasma concentrations are only 7% of those seen with the parent compound ([DeVane et al. 2002](#)). However, the ratios of mCPP to nefazodone concentrations in the brain are 47:1 and 10:1 in the mouse and rat, respectively. Brain concentrations of hydroxynefazodone in the rat are less than 10% of those in plasma, suggesting very poor blood–brain barrier penetration. Thus, despite its relatively lower plasma concentrations, mCPP has substantial presence in the brain,

whereas the in vivo activity of hydroxynefazodone may be mostly the result of its biotransformation to mCPP ([Nacca et al. 1998](#)).

Nefazodone has nonlinear kinetics, which results in greater than proportional mean plasma concentrations with higher doses. Nefazodone is extensively (99%) but loosely protein bound ([Bristol-Myers Squibb 2003](#)). In patients with hepatic cirrhosis, single-dose nefazodone and hydroxynefazodone levels are about twice as high as in healthy volunteers, but the difference decreases to approximately 25% at steady state. Exposure to mCPP is about two- to threefold greater in patients with cirrhosis, and exposure to triazole dione is similar after a single dose and at steady state ([Barbhaiya et al. 1995](#)).

## Mechanism of Action

The mechanism of action of nefazodone is poorly understood. The manufacturer has indicated that nefazodone antagonizes 5-HT<sub>2</sub> receptors and also inhibits neuronal uptake of both 5-HT and NE ([Bristol-Myers Squibb 2003](#)). Several reviews refer to nefazodone as a “dual acting” antidepressant, suggesting that it enhances both serotonergic and noradrenergic neurotransmission via uptake blockade. Although nefazodone has similar effects on the 5-HT and NE transporters, this observation is potentially misleading. Nefazodone’s inhibition of NE reuptake is weaker than that of the SSRI fluoxetine and is approximately three orders of magnitude weaker than what is seen with conventional NE reuptake inhibitors. Furthermore, nefazodone’s inhibition of 5-HT reuptake is nearly identical to that of desipramine and more than 100-

fold less than that of fluoxetine ([Bolden-Watson and Richelson 1993](#)). Thus, the “dual action” of nefazodone refers to minimal, albeit equal, effects on 5-HT and NE reuptake inhibition.

In humans, therapeutic doses of nefazodone do not cause sustained 5-HT uptake inhibition at the platelet 5-HTT ([Narayan et al. 1998](#)). The active metabolite m-CCP, which appears to predominate in the brain because of greater penetration of the blood-brain barrier ([Nacca et al. 1998](#)), may play an important role in the mechanism of action.

## Indications and Efficacy

In three of four Phase III imipramine- and placebo-controlled studies, nefazodone was found to be an effective antidepressant with similar efficacy to imipramine; in one of these studies, neither active drug had significantly greater efficacy than did placebo. The incidence of premature treatment discontinuation and side effects was higher for the imipramine group than for the nefazodone treatment group ([Rickels et al. 1995](#)). In double-blind studies without placebo control groups, there were no significant differences in the clinical responses to nefazodone and sertraline or paroxetine in outpatients with depression ([Feiger et al. 1996](#)). Hospitalized patients with severe major depressive disorder had higher response rates to nefazodone compared with placebo ([Feighner et al. 1998](#)). In patients with moderate to severe major depression, the efficacy of amitriptyline was clearly superior to that of nefazodone ([Ansseau et al. 1994](#)). [Keller et al. \(2000\)](#) compared nefazodone, cognitive-behavioral therapy (CBT), and a combination of these two treatments in a double-blind

study of patients with chronic major depressive disorder. Each monotherapy yielded a response rate of 48%, whereas the combined treatment had a greater efficacy (73%). When patients who failed to respond to 12 weeks of treatment with either nefazodone or cognitive-behavioral analysis system psychotherapy are then switched to the other treatment, significant symptom improvement is achieved ([Schatzberg et al. 2005](#)). Nefazodone has also been shown to be effective in the continuation phase of treatment in double-blind studies ([Baldwin et al. 2001](#); [Feiger et al. 1999](#)).

In a double-blind, placebo-controlled study, nefazodone was found to be safe and effective in the treatment of depression in patients with alcohol dependence, although it did not add any advantage over psychoeducational group intervention in terms of drinking outcomes ([Roy-Byrne et al. 2000](#)). A double-blind, controlled study found that nefazodone was not efficacious for the treatment of alcohol dependence ([Kranzler et al. 2000](#)). A randomized, placebo-controlled, double-blind multicenter study compared nefazodone versus placebo and CBT versus nondirective group counseling (GC) for relapse prevention in alcohol dependence. Two hundred forty-two male patients received either nefazodone plus GC or CBT or placebo plus GC or CBT. There were no differences among the four groups in cumulative days of abstinence or amount of alcohol consumed during specified time periods during the initial 12-week study phase. After 1 year, the only significant difference among the groups was higher alcohol consumption in the nefazodone plus GC group, raising concerns that nefazodone may potentially increase the risk of relapse ([Wetzel et al. 2004](#)). Other potential clinical applications for nefazodone have been explored, including

treatment of PTSD (for which it is considered a second-line agent) ([Jeffreys et al. 2012](#)); however, nefazodone's current use is relatively limited.

The usual starting dosage of nefazodone is 200 mg/day in two divided doses. The suggested dosage range is 300–600 mg/day. Increases should be in increments of 100–200 mg/day at weekly intervals. The starting dosage in elderly or debilitated patients should be lowered to 100 mg/day, taken in two divided doses, and the rate of titration should be adjusted accordingly ([Bristol-Myers Squibb 2003](#)). [Zajack et al. \(2002\)](#) reported that in studies comparing low-dosage (50–250 mg/day) and high-dosage (100–500 mg/day) nefazodone, better clinical response was obtained in the latter group, and the mean effective dosage ranged from 375 mg/day to 460 mg/day. A lower starting dose should be considered when switching to nefazodone from an SSRI if a full washout has not been completed. Once-daily bedtime dosing appears to be well tolerated and effective.

## Side Effects and Toxicology

In initial clinical trials that included approximately 2,250 patients, side effects more frequently associated with nefazodone than with placebo included dizziness, asthenia, dry mouth, nausea, and constipation ([Fontaine 1993](#)).

[Preskorn \(1995\)](#) found that the total cumulative incidence of treatment-emergent adverse effects for nefazodone was lower than that of imipramine or fluoxetine. The most common placebo-adjusted adverse effects associated with nefazodone were dry mouth, somnolence, dizziness, nausea, constipation, blurred vision, and postural

hypotension. Nefazodone appears to have advantages over SSRIs in terms of treatment-associated sexual dysfunction ([Clayton et al. 2014](#); [Ferguson et al. 2001](#)).

There are now well-publicized concerns regarding the association of nefazodone with liver toxicity and liver failure, including fatalities ([Choi 2003](#); [Voican et al. 2014](#)). In 2001 the manufacturer added a black box warning to the package insert, describing a reported rate of life-threatening liver failure in the United States of 1 case per 250,000–300,000 patient-years of nefazodone treatment. In 2004 Serzone was withdrawn from the U.S. market, following its withdrawal from several international markets. The generic drug remains available in the United States. In a review of 1,338 humans with exposure to nefazodone overdoses, there were no reported deaths. The most common serious clinical effect was hypotension, reported in 1.6% of cases ([Benson et al. 2000](#)).

## Drug–Drug Interactions

The manufacturer of triazolam warns that its concurrent use with nefazodone is contraindicated. Increases in the plasma concentration of digoxin occur with concurrent nefazodone administration. Nefazodone increases the plasma concentrations of terfenadine and loratadine (with associated QTc prolongation), carbamazepine, and cyclosporine.

---

## Conclusion

---

Trazodone was one of the earliest second-generation antidepressants. Its lack of anticholinergic effects provided an advantage over the TCAs for many patients; its sedative properties are helpful for some patients but problematic for others; and orthostatic hypotension is a concern for elderly patients. Nefazodone is related to trazodone, and the two drugs share an active metabolite, mCPP, that may play an important role in their mechanism of action. The risk of serious liver damage led to Serzone's removal from the market in several countries, although generic nefazodone is currently available in the United States.

## CHAPTER 16

### Vortioxetine

Pierre Blier, M.D., Ph.D.

#### History and Discovery

Vortioxetine, formerly designated Lu AA 21004, was developed by Lundbeck in an attempt to add to a selective serotonin (5-hydroxytryptamine [5-HT]) reuptake inhibitor (SSRI) additional properties, namely, 5-HT<sub>1A</sub> and 5-HT<sub>3</sub> receptor affinities ([Bang-Andersen et al. 2011](#)). These pharmacological targets were based on the premises that the antidepressant effect of SSRIs can be enhanced by combining them with a partial 5-HT<sub>1A</sub> agonist and that 5-HT<sub>3</sub> antagonists are antiemetic drugs, nausea being a common side effect of SSRIs ([Sanchez et al. 2015](#)). In 2013, vortioxetine, marketed under the brand name Brintellix, received approval from the U.S. Food and Drug Administration (FDA) and the European Medicines Agency for the treatment of major depressive disorder ([Takeda Pharmaceuticals America 2016](#)). In the United States, at the behest of the FDA, the brand name was subsequently changed to Trintellix to avoid confusion with the anticoagulant drug Brilinta (ticagrelor).

#### Structure-Activity Relations

Vortioxetine is a piperazine derivative, and its chemical name is 1-[2-(2,4-dimethylphenyl)sulfanyl]-phenyl]-piperazine ([Figure 16-1](#)).

**FIGURE 16-1.** Chemical structure of vortioxetine.

The medication is produced in the form of a hydrobromide salt.

---

## Pharmacological Profile

---

Vortioxetine is described as a multimodal serotonin agent because it acts on two types of neuronal elements: the 5-HT transporter and several 5-HT receptor subtypes ([Zohar et al. 2015](#)). Among monoamine transporters, it binds selectively to the 5-HT transporter, but only to the same extent as other SSRIs at its maximum recommended dosage, as shown in positron emission tomography studies in humans ([Areberg et al. 2012](#); [Meyer et al. 2004](#); [Stenkrona et al. 2013](#)). Vortioxetine is a 5-HT<sub>3</sub> antagonist, a full 5-HT<sub>1A</sub> agonist, a 5-HT<sub>7</sub> antagonist, a partial 5-HT<sub>1B</sub> agonist, and a 5-HT<sub>1D</sub> antagonist ([Mørk et al. 2012](#)). On the basis of plasma levels and affinity values, all of these targets could be engaged by vortioxetine to physiologically relevant levels within its usual therapeutic dosage range. Although the clinical significance of these various activities at 5-HT receptors in the presence of lower occupancy of 5-HT transporters has not been determined, synergies between such neuronal elements on neurotransmitter levels have been documented in the brains of laboratory animals ([Sanchez et al. 2015](#)).

---

## Pharmacokinetics and Disposition

---

Vortioxetine is well absorbed from the gastrointestinal tract, and its bioavailability is similar under fasting and fed conditions. It reaches peak plasma concentrations in 7–11 hours and is 98% bound to plasma proteins. Vortioxetine is not a substrate for the permeability glycoproteins, indicating that brain levels will not be affected by possible polymorphisms of these efflux carriers. The terminal half-life of vortioxetine is about 66 hours, and steady-state concentrations are achieved after 2 weeks; consequently, complete elimination requires 2 weeks as well ([Areberg et al. 2014](#); [Bundgaard et al. 2016](#)).

Vortioxetine is extensively metabolized through oxidation and subsequently by glucuronic conjugation. The cytochrome P450 (CYP) 2D6 isoenzyme is the main enzyme catalyzing its catabolism to its major carboxylic acid metabolite, which is pharmacologically inactive. About two-thirds of the inactive metabolites are excreted in the urine, and the last third are excreted in the feces. A very small amount of unchanged vortioxetine is excreted in the urine. No dosage adjustment is necessary in patients with renal impairment or mild to moderate hepatic impairment; however, vortioxetine is not recommended in patients with severe hepatic insufficiency. The plasma levels of vortioxetine are about two times higher in poor metabolizers of CYP2D6 ([Chen et al. 2013](#)).

## Indications and Efficacy

---

At present, major depressive disorder is the only approved indication for vortioxetine worldwide. However, vortioxetine's efficacy has also been examined in generalized anxiety disorder. Of the five short-term placebo-controlled studies and one large relapse prevention trial conducted ([Fu et al. 2016](#)), one short-term trial ([Bidzan et al. 2012](#)) and the relapse prevention trial ([Baldwin et al. 2012b](#)) reported positive findings. Although

methodological issues may have been at play in the failed trials, there is not yet enough evidence to proceed with a vortioxetine indication for generalized anxiety disorder.

In contrast, the clinical development program for vortioxetine in major depressive disorder has been successful: thus far, 8 of the 12 placebo-controlled short-term studies, including one in elderly patients, have reported positive results, and a 24-week double-blind relapse prevention study also reported positive findings (Boulenger et al. 2012; Katona et al. 2012; Mahableshwarkar et al. 2015; McIntyre et al. 2014; Sanchez et al. 2015). Five of these studies included an active comparator—venlafaxine in one study, and duloxetine in the other four studies. Among patients participating in the acute studies, 2,080 received a placebo, 140 received 1 mg/day, 308 received 2.5 mg/day, 1,014 received 5 mg/day, 969 received 10 mg/day, 599 received 15 mg/day, and 615 received 20 mg/day (Table 16-1). On the basis of such results, the recommended effective dosage range is 5–20 mg/day. In adults ages 18–65 years, the usual recommended starting dosage is 10 mg/day, usually taken in the morning after a meal for convenience, but it can also be taken at night. In elderly patients, the starting dosage should be 5 mg/day. Although in the controlled studies the dosage was commonly increased after 1 week, in clinical practice a minimum of 2 weeks should elapse before an up-titration is implemented, mainly because this is the interval needed to achieve a steady-state concentration. One open-label study has assessed the safety, tolerability, and maintained effectiveness of vortioxetine in 535 patients with major depressive disorder over 52 weeks (Baldwin et al. 2016).

One double-blind study examined the efficacy and tolerability of vortioxetine in 493 patients with major depressive disorder who had not responded adequately to an SSRI or a serotonin-norepinephrine reuptake inhibitor (SNRI) (Montgomery et al. 2014). In this study, patients were asked to decrease their current drug regimen to the minimum effective dosage in the week prior to being randomly assigned to either vortioxetine or the melatonin receptor agonist/5-HT<sub>2B/2C</sub> antagonist agomelatine. Both agents could be titrated to their maximum recommended dosages. The researchers found that vortioxetine was statistically superior to agomelatine.

It is important to mention that three short-term trials examined cognitive function with a battery of tests, one in elderly patients and two with a primary outcome measure being improvement in cognitive function. All three trials yielded positive antidepressant action above placebo (Katona et al. 2012; Mahableshwarkar et al. 2015; McIntyre et al. 2014). Vortioxetine demonstrated a significantly greater effect than placebo on the Digit Symbol Substitution Task (DSST; a pencil-and-paper task that assesses attention, speed of processing, and executive function) in all three studies. In contrast, duloxetine (60 mg/day) showed no significant effect on the DSST versus placebo in the two studies that used this medication as a comparator (Katona et al. 2012; Mahableshwarkar et al. 2015). Furthermore, vortioxetine’s beneficial effect on cognition was deemed through path

analysis to be mostly a direct effect that was independent of the drug's antidepressant effect. One study used more routine daily tasks (the University of California San Diego Performance-Based Skills Assessment), and vortioxetine but not duloxetine separated from placebo, with the difference being almost entirely attributable to a direct effect ([Mahableshwarkar et al. 2015](#)). Taken together, the results of these studies led the European Medicines Agency, but not the FDA, to label vortioxetine for the treatment of cognitive dysfunction associated with major depressive disorder ([McIntyre et al. 2016](#)). There are, however, no studies reporting this putative benefit in patients with other diagnoses.

---

## Side Effects and Toxicity

---

The main side effect of vortioxetine on treatment initiation is nausea, which occurs at about the same rate as with SSRIs and SNRIs, generally in about a quarter to a third of patients ([Citrome 2014](#)). This finding is somewhat surprising because vortioxetine is a potent 5-HT<sub>3</sub> receptor antagonist, which should prevent any nausea resulting from 5-HT reuptake inhibition. However, nausea can be produced by a variety of chemical actions, including opioid and dopamine receptor activation and, importantly, 5-HT<sub>1A</sub> receptor agonism (as is the case with the 5-HT<sub>1A</sub> receptor agonist buspirone). The latter effect is likely responsible for the transient nausea reported during the initial 2 weeks of vortioxetine administration, given the drug's potent 5-HT<sub>1A</sub> receptor agonism. This side effect led to treatment discontinuation in 1%–4% of subjects and appeared to be dose dependent ([Baldwin et al. 2016](#)).

Apart from gastrointestinal side effects, other side effects were generally not markedly different from those reported in the placebo group. Overall, discontinuation due to treatment-emergent adverse events was dose dependent and was between 4.5% and 8.5%, reaching the same level as with 60 mg/day of duloxetine, the placebo rate being 3.5% ([Baldwin et al. 2016](#)). When side effects are problematic, vortioxetine should be withheld for 3 days (given its long half-life) and restarted at half the previous daily dosage.

Vortioxetine has not been found to produce clinically meaningful effects on body weight in short-term and long-term clinical studies. It was not associated with an increased incidence of insomnia or daytime somnolence above the placebo level, in contrast to venlafaxine, which produced greater rates of insomnia, and duloxetine, which produced greater rates of somnolence. There are no significant discontinuation symptoms associated with abrupt cessation of vortioxetine, as expected from its long terminal half-life.

Sexual dysfunction is a classic side effect of drugs that potently inhibit the 5-HT transporter. For patients receiving vortioxetine 5 mg/day or 10 mg/day, rates of sexual dysfunction (as measured on the Arizona Sexual Experiences Scale) did not differ from rates for patients receiving placebo; however, for patients receiving vortioxetine 20 mg/day, rates of sexual dysfunction were equivalent to rates for patients receiving duloxetine 60 mg/day ([Baldwin et al. 2016](#)). These results are consistent with the lower occupancy of the 5-HT transporter with vortioxetine at dosages lower than 20 mg/day, which is about the same as with duloxetine 60 mg/day (i.e., 80%; [Takano et al. 2006](#)). In one study, 477 patients with major depressive disorder who were responding to paroxetine, sertraline, or citalopram but were experiencing treatment-emergent sexual dysfunction were switched to either vortioxetine or escitalopram (dosages for both drugs: 10 mg/day or 20 mg/day) ([Jacobsen et al. 2015a](#)). As measured by the Changes in Sexual Functioning Questionnaire Short Form (CSFQ-14), vortioxetine-treated patients showed

significant improvements in comparison with escitalopram-treated patients on four of five dimensions and all three phases of sexual functioning assessed by the CSFQ-14. Although the absolute difference between the two groups was significant, it is important to note that three-quarters of the patients receiving vortioxetine were taking the higher dosage (20 mg/day).

No cases of vortioxetine overdose have been reported in the literature. A supratherapeutic dosage of 40 mg/day for 14 days did not produce clinically relevant electrocardiography or hemodynamic changes (i.e., QTc prolongation of 5 milliseconds) (Wang et al. 2013).

---

## Drug-Drug Interactions

---

Vortioxetine must never be coadministered with a monoamine oxidase inhibitor (MAOI). Before a patient is started on vortioxetine, there must be an elimination period of 14 days for an irreversible MAOI or 2 days for the reversible MAOI moclobemide. Similarly, a 14-day elimination period for vortioxetine is necessary before initiating either an irreversible MAOI or moclobemide.

Vortioxetine is neither an inhibitor nor an inducer of any metabolic enzymes. Consequently, it will not alter the levels of other medications through metabolic interference. Complete inhibitors of CYP2D6, such as fluoxetine and paroxetine, as well as moderate inhibitors, such as bupropion and duloxetine, will approximately double the exposure (area under the curve) to vortioxetine. These interactions are expected to occur mainly in switch situations, which are discussed in the following section. In such concomitant regimens, the vortioxetine dosage should be reduced by half (D'Empaire et al. 2011; Hvenegaard et al. 2012).

Triptans used in the treatment of migraines may be less effective in the presence of vortioxetine. This class of agents acts mainly by activating 5-HT<sub>1D</sub> receptors, whereas vortioxetine is a 5-HT<sub>1D</sub> receptor antagonist. However, because vortioxetine's affinity for the 5-HT<sub>1D</sub> receptor is very low compared with its affinities for other 5-HT receptor subtypes (Mørk et al. 2012), the dampened activity of triptans may not occur with lower dosages of vortioxetine.

---

## Switching Strategies for Vortioxetine

---

Despite an extensive clinical program, there are only two studies reported on switching to vortioxetine from SSRIs and SNRIs (Jacobsen et al. 2015a; Montgomery et al. 2014). Although patients seemed to tolerate the transition to vortioxetine well, in clinical practice the switch process has been more problematic. It is likely that premature discontinuations of vortioxetine stem more from an abrupt, or a too-rapid, dosage decrease of the SSRI or SNRI than from the effects of vortioxetine itself (Rosenbaum and Zajecka 1997). As illustrated in Figure 16-2, SSRIs or SNRIs are eliminated within several days, thereby rapidly decreasing the occupancy of the 5-HT transporters, but vortioxetine steady-state plasma concentrations are achieved only after 2 weeks, producing a receptor occupancy of about 60% at 10 mg/day and 80% at 20 mg/day. Consequently, discontinuation symptoms could occur during a rapid switch that could be exacerbated by the potent 5-HT<sub>1A</sub> agonistic profile of vortioxetine. Therefore, implementation of a gradual crossover strategy

is recommended when switching a patient from SSRIs or SNRIs to vortioxetine. One exception would be a switch from fluoxetine, because of its long half-life. However, because fluoxetine is a CYP2D6 inhibitor, the initial dosage of vortioxetine should be 5 mg/day, and the dosage should be gradually increased as fluoxetine is slowly eliminated.

**FIGURE 16-2.** Relationship between occupancy of the serotonin transporter by various drugs used to treat depression and minimum time following their discontinuation and the introduction of vortioxetine.

The lines represent the decrease of serotonin (5-hydroxytryptamine [5-HT]) transporter occupancy following an abrupt cessation of the selective serotonin reuptake inhibitors escitalopram and fluoxetine and the serotonin-norepinephrine reuptake inhibitor venlafaxine in comparison with the rise of 5-HT transporter occupancy following the initiation of the multimodal agent vortioxetine at a dosage of 5–10 mg/day. When most 5-HT reuptake inhibitors (with the exception of fluoxetine) are discontinued abruptly before starting vortioxetine, discontinuation phenomena may be triggered, leading to an apparent intolerance of vortioxetine. Therefore, the previous medication should be gradually decreased while vortioxetine levels are building up.

## Conclusion

Vortioxetine is a multimodal serotonergic agent that inhibits the 5-HT transporter, albeit to a lesser extent than other SSRIs, and has a variety of actions at five 5-HT receptor subtypes. Its only approved indication is for the treatment of major depressive disorder. Although it may produce as much mild to moderate nausea as SSRIs on treatment initiation, this effect is generally transient and seldom leads to treatment discontinuation. At dosages of 10 mg/day or less, vortioxetine is expected to produce less sexual dysfunction than SSRIs and SNRIs. Vortioxetine does not impact the cardiovascular system, even at twice its maximum recommended dosage. Vortioxetine will not alter the levels of other medications because it is not a hepatic enzyme inducer or inhibitor. It is still too early to determine vortioxetine's role in treatment-resistant depression. However, in

some patients with major depressive disorder, vortioxetine may exert a beneficial action on cognitive functioning.

# CHAPTER 17

## Mirtazapine

Alan F. Schatzberg, M.D.

---

### History and Discovery

---

Mirtazapine, originally known as ORG 3770, was first synthesized in the Netherlands by the Department of Medicinal Chemistry of NV Organon ([Kaspersen et al. 1989](#)). First approved for use in major depressive disorder in the Netherlands in 1994, mirtazapine was introduced in the United States in 1996.

---

### Structure-Activity Relations

---

Mirtazapine ([Figure 17-1](#)) is a member of the piperazinoazepines, a class of chemical compounds that is unrelated to any other class used in the treatment of psychiatric conditions ([Maris et al. 1999](#)). Mirtazapine is also known by its chemical name, 1,2,3,4,10,14b-

hexahydro-2-methylpyrazino[2,1-a]pyridol[2,3-c]benzazepine ([Dahl et al. 1997](#); [Dodd et al. 2000](#)).

---

**FIGURE 17-1.** Chemical structure of mirtazapine.

---

## Pharmacological Profile

---

Mirtazapine is described as a noradrenergic and specific serotonergic antidepressant (NaSSA) ([Holm and Markham 1999](#); [Kent 2000](#); [Nutt 1998](#)). It is a potent serotonin<sub>2</sub> (5-HT<sub>2</sub>), serotonin<sub>3</sub> (5-HT<sub>3</sub>), and central  $\alpha_2$ -adrenergic receptor antagonist ([de Boer 1996](#); [De Boer et al. 1995](#); [Kooyman et al. 1994](#)). Antagonism of 5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptors results in an increase in serotonin<sub>1A</sub> (5-HT<sub>1A</sub>) receptor-mediated transmission and, thus, a more specific effect on serotonergic transmission, relative to the selective serotonin reuptake inhibitor (SSRI) class of antidepressants ([Bengtsson et al. 2000](#); [Berendsen and Broekkamp 1997](#); [Kent 2000](#)). In addition, because  $\alpha_2$ -adrenergic receptors normally act to inhibit transmission at serotonergic and noradrenergic axon terminals, mirtazapine acts to increase the release of both serotonin (5-HT) and norepinephrine via blockade of central  $\alpha_2$  receptors ([Numazawa et al. 1995](#)).

Mirtazapine has no significant affinity for dopamine receptors, low affinity for muscarinic cholinergic receptors ([de Boer 1996](#)), and high affinity for histamine<sub>1</sub> (H<sub>1</sub>) receptors ([de Boer 1996](#)). Mirtazapine appears to have no effect on 5-HT and dopamine reuptake and only a minimal effect on norepinephrine reuptake ([de Boer 1996](#); [Kent 2000](#)). The drug appears to significantly reduce cortisol levels ([Laakmann et al. 2004](#); [Schmid et al. 2006](#)).

---

## Pharmacokinetics and Disposition

---

### Absorption

Mirtazapine is well absorbed from the gastrointestinal tract, and bioavailability does not appear to be affected by the presence of food in the stomach ([Fawcett and Barkin 1998b](#)). An oral rapidly disintegrating tablet has been available since 2001 ([Benkert et al. 2006](#)).

### Distribution

Mirtazapine appears to be 85% bound to plasma proteins ([Fawcett and Barkin 1998b](#)).

### Metabolism

Mirtazapine is primarily metabolized by the liver via demethylation and hydroxylation, followed by

glucuronidation ([Fawcett and Barkin 1998b](#); [Merck & Co., Inc. 2016](#)). Its major metabolite, desmethyilmirtazapine, is weakly active but is present in lower serum concentrations than the parent compound ([Fawcett and Barkin 1998b](#); [Kent 2000](#)). Mirtazapine lacks both autoinduction and autoinhibition of hepatic cytochrome P450 (CYP) enzymes ([Fawcett and Barkin 1998b](#)). Although in vitro studies do not demonstrate an inhibitory effect, mirtazapine is a substrate for CYP1A2, 2D6, and 3A4 ([Fawcett and Barkin 1998b](#); [Merck & Co., Inc. 2016](#)). Mirtazapine is a mild competitive inhibitor of CYP2D6 ([Barkin et al. 2000](#); [Fawcett and Barkin 1998b](#)). A pharmacogenetic study of CYP2D6 in geriatric depressed patients failed to reveal that slow and intermediate metabolizers demonstrate increased dropout rates due to side effects of the drug ([Murphy et al. 2003b](#)).

These findings suggest that mirtazapine is well tolerated in individuals who are slow metabolizers of CYP2D6.

## Elimination

Mirtazapine and its metabolites are eliminated primarily in the urine (up to 75%) and feces (up to 15%) ([Fawcett and Barkin 1998b](#)). The elimination half-life of mirtazapine is 20–40 hours ([Fawcett and Barkin 1998b](#); [Merck & Co., Inc. 2016](#); [Stimmel et al. 1997](#)). Of note, the clearance of mirtazapine may be affected by hepatic or renal impairment ([Fawcett and Barkin 1998b](#)). The elimination half-life may increase by 30%–40% in patients with hepatic impairment ([Fawcett and Barkin 1998b](#); [Kent 2000](#)). In patients with moderate to severe renal impairment, the clearance of mirtazapine may be decreased by 30%–50%

([Fawcett and Barkin 1998b](#); [Kent 2000](#); [Merck & Co., Inc. 2016](#)).

## Indications and Efficacy

---

### Major Depressive Disorder

Pooled data from the 6-week U.S. clinical trials that were part of the new drug application showed that approximately 50% of mirtazapine-treated patients and 20% of placebo-treated patients achieved at least a 50% improvement in scores on the Hamilton Rating Scale for Depression (Ham-D) ([Fawcett and Barkin 1998b](#)).

In a randomized, double-blind, placebo-controlled study of 90 outpatients with a major depressive episode, mirtazapine treatment resulted in clinically significant reductions in Ham-D scores by study endpoint at 6 weeks, although improvement was noted as early as the first week ([Claghorn and Lesem 1995](#)).

A meta-analysis of four randomized, double-blind 6-week studies demonstrated that mirtazapine was as effective as amitriptyline in the treatment of major depressive disorder but had significantly fewer anticholinergic, serotonergic, and cardiovascular adverse effects ([Stahl et al. 1997](#)).

In a randomized, double-blind multicenter study comparing mirtazapine and fluoxetine, both medications were found to be well tolerated in the treatment of major depressive disorder, although mirtazapine was noted to demonstrate a significantly greater improvement in Ham-D scores, beginning in the third week of treatment ([Wheatley et al. 1998](#)).

When mirtazapine was compared with paroxetine in a randomized, double-blind study of 275 patients with major depressive disorder, the two drugs were found to be equally well tolerated and efficacious overall, but mirtazapine-treated patients had significantly lower Ham-D and Hamilton Anxiety Scale (Ham-A) scores at week 1, possibly suggesting a faster onset of therapeutic benefit from mirtazapine ([Benkert et al. 2000](#)).

Similarly, when compared with citalopram in an 8-week randomized, double-blind multicenter study of 270 patients with major depressive disorder, mirtazapine was equally well tolerated and efficacious at study endpoint but was significantly more effective (as assessed by Ham-A, Montgomery-Åsberg Depression Rating Scale [MADRS], and Clinical Global Impression [CGI] Scale scores) at week 2 ([Leinonen et al. 1999](#)).

Of interest, in an 8-week randomized, double-blind multicenter study comparing two antidepressants with both serotonergic and noradrenergic activity, mirtazapine was found to be equal in efficacy to venlafaxine in the treatment of major depressive disorder with melancholic features, although it demonstrated a trend (not statistically significant) toward a higher percentage of responders and remitters ([Guelfi et al. 2001](#)).

In a meta-analysis of 15 studies comparing mirtazapine with an SSRI, [Thase et al. \(2010\)](#) concluded that mirtazapine was significantly more likely than the SSRI to induce remission at weeks 1, 2, 4, and 6. At week 2, the remission rates with mirtazapine were more than 70% higher than those with the SSRI, suggesting more rapid effects.

A study that investigated several antidepressant combinations versus monotherapy found that mirtazapine

coadministered with fluoxetine was significantly more effective than fluoxetine alone. Similarly high rates of remission were observed for mirtazapine coadministered with bupropion and mirtazapine coadministered with venlafaxine ([Blier et al. 2010](#)).

In contrast to the findings of the [Blier et al. \(2010\)](#) study, the National Institute of Mental Health (NIMH)-funded Combination Medication to Enhance Depression Outcomes (CO-MED) study—in which remission and response rates for two antidepressant combinations (escitalopram plus bupropion sustained release (SR) and venlafaxine plus mirtazapine) administered from treatment initiation were compared with those for antidepressant monotherapy (escitalopram plus placebo)—failed to detect differences between the groups ([Rush et al. 2011](#)). Baseline insomnia was not a predictor of response to single versus combination antidepressants ([Sung et al. 2015](#)).

The sleep effects of mirtazapine in major depressive disorder were reported by [Schmid et al. \(2006\)](#). Mirtazapine improved sleep continuity by day 2 of therapy, and the effect was sustained for at least 4 weeks. At day 28, significant increases in slow-wave and low-delta sleep were also observed.

An 8-week open-label trial of mirtazapine in 22 menopausal patients receiving estrogen replacement therapy who had major depressive disorder demonstrated an almost 90% remission rate among the study completers ([Joffe et al. 2001](#)).

## **Patients With Insufficient Response to Selective Serotonin Reuptake Inhibitor Treatment**

In an 8-week open-label study of 103 outpatients with DSM-IV ([American Psychiatric Association 1994](#)) major depressive disorder complicated by lack of response to (or intolerance of) treatment with fluoxetine, paroxetine, or sertraline, approximately one-half of the outpatients demonstrated a 50% reduction in the 17-item Ham-D (Ham-D-17) score when switched to treatment with mirtazapine ([Fava et al. 2001](#)).

In a 4-week study of patients with persistent major depressive disorder despite adequate antidepressant monotherapy, augmentation with mirtazapine resulted in a 45% remission rate, compared with a 13% remission rate among patients receiving placebo ([Carpenter et al. 2002](#)). Of note, in this study there were no significant differences in side effects between drug and placebo ([Carpenter et al. 2002](#)).

In level 3 of the Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) trial, mirtazapine was compared with nortriptyline in patients whose symptoms had not responded to two previous consecutive antidepressant trials ([Fava et al. 2006](#)). Level 1 of STAR\*D employed citalopram; level 2 employed a switch to another drug or augmentation. Nortriptyline produced higher remission rates than did mirtazapine (19.8% vs. 12.3%); however, the difference was not statistically significant.

## **Patients With Depression and Sexual Dysfunction**

In an open-label study of 103 patients with depression treated with mirtazapine, 54% of patients who had reported poor or very poor sexual functioning during prior

treatment with an SSRI described an improvement in sexual functioning by study endpoint ([Fava et al. 2001](#)).

Similarly, [Gelenberg et al. \(2000\)](#) reported that 58% of patients with prior SSRI-induced sexual dysfunction had a return of normal sexual functioning when they switched to treatment with mirtazapine.

In contrast, augmentation with mirtazapine was no more effective than placebo augmentation in reversing SSRI-associated sexual side effects in patients with fluoxetine-associated sexual dysfunction ([Michelson et al. 2002](#)).

## **Depression in Elderly Patients**

In a 6-week study of 150 outpatients (ages 55–80 years) with moderate to severe depression, mirtazapine was found to be effective and well tolerated ([Halikas 1995](#)). Half of the mirtazapine-treated patients and 35% of the placebo-treated patients demonstrated at least a 50% reduction in Ham-D score ([Halikas 1995](#)). In another blinded study, mirtazapine was significantly more effective than paroxetine at weeks 1, 2, 3, and 6, but not at week 8, in subjects older than 65 years ([Schatzberg et al. 2002](#)). Differences were observed primarily on measures of anxiety and sleep. Apolipoprotein epsilon 4 (*ApoE-ε4*) carrier status predicted a positive response to mirtazapine ([Murphy et al. 2003a](#)).

The oral disintegrating tablet formulation of mirtazapine has been studied in elderly patients and appears to be well tolerated ([Nelson et al. 2007](#); [Varia et al. 2007](#)).

## **Patients With Comorbid or Primary Symptoms of Anxiety**

Meta-analyses of placebo-controlled studies of patients with depression and associated symptoms of anxiety have demonstrated that mirtazapine-treated patients exhibit significantly greater improvement in symptoms of anxiety compared with placebo-treated patients ([Fawcett and Barkin 1998a](#); [Nutt 1998](#)), beginning as early as the first week of treatment ([Fawcett and Barkin 1998a](#)).

In an 8-week open-label study of 10 patients with major depressive disorder and comorbid generalized anxiety disorder, mirtazapine treatment resulted in significant decreases in Ham-D and Ham-A scores, with improvement beginning as early as the first week of treatment ([Goodnick et al. 1999](#)).

## Dysthymia

In a 10-week open-label trial of the use of mirtazapine in 15 patients with DSM-IV dysthymic disorder, 8 patients demonstrated at least a 40% reduction in Ham-D scores, and 4 of these 8 patients showed symptom remission by study endpoint ([Dunner et al. 1999](#)).

## Social Anxiety Disorder (Social Phobia)

Mirtazapine was compared with placebo in a 10-week double-blind comparison study in 66 women with social phobia. Mirtazapine appeared to separate from placebo on several primary measures of social phobia symptoms ([Muehlbacher et al. 2005](#)).

# Generalized Anxiety Disorder

In an open-label trial of mirtazapine treatment in 44 adult patients with generalized anxiety disorder, response criteria were achieved in 80% of patients ([Gambi et al. 2005](#)). Controlled trial data are not available.

# Obsessive-Compulsive Disorder

[Koran et al. \(2005\)](#) reported on a two-phase study (a 12-week open-label phase followed by an 8-week double-blind discontinuation phase) of mirtazapine (maximum dosage of 60 mg/day) in 30 patients with obsessive-compulsive disorder (OCD). In the 8-week discontinuation phase, mirtazapine was significantly more effective than placebo in preventing symptom recurrence.

Mirtazapine augmentation of citalopram was assessed in 49 nondepressed OCD patients ([Pallanti et al. 2004](#)). Subjects were treated with citalopram plus placebo or citalopram plus mirtazapine under single-blind conditions. Mirtazapine appeared to speed the response to citalopram but not to improve overall response.

# Posttraumatic Stress Disorder

In an 8-week open-label study of 6 patients with severe chronic posttraumatic stress disorder (PTSD), mirtazapine treatment resulted in one-half of the patients demonstrating at least a 50% reduction on the CGI score and significant reductions on scales of PTSD severity ([Connor et al. 1999](#)).

In a 6-week double-blind comparison study, mirtazapine was compared with sertraline in Korean veterans with PTSD ([Chung et al. 2004](#)). At study endpoint, mirtazapine was statistically significantly superior to sertraline on several measures. Efficacy was apparently maintained to 24 weeks ([Kim et al. 2005](#)).

## Alcohol Use Disorder

Mirtazapine was not found to be significantly superior to placebo in reducing alcohol use in a study of men with high alcohol consumption ([de Bejczy and Söderpalm 2015](#)), although there was a suggestion that the drug might be helpful in subjects with a family history of alcohol use disorder.

## Sleep Disorders

Because of its sedating properties in depression, mirtazapine has been studied in patients with breathing-related sleep disorders. In a double-blind crossover study in 7 patients with obstructive sleep apnea, mirtazapine at dosages of 4.5 mg/day and 15 mg/day produced significantly greater reductions (on the order of 46%–52%) in apnea-hypopnea index (AHI) scores in comparison with placebo ([Carley et al. 2007](#)). However, because of concerns regarding weight gain and sedation, the authors concluded that mirtazapine could not at present be recommended as a primary therapy in this disorder.

## Chronic or Recurrent Pain

A number of case reports indicate that mirtazapine could be beneficial in chronic or recurrent pain ([Brannon and Stone 1999](#); [Brannon et al. 2000](#); [Kuiken et al. 2005](#); [Nutt and Law 1999](#)).

In a large observational study conducted in Germany ([Freynhagen et al. 2006](#)) and involving 600 patients with comorbid pain and depression treated with mirtazapine, the drug appeared to reduce pain effectively, with a relatively low-order risk of side effects (7%) at a mean dosage of 35 mg/day.

Mirtazapine at 15–30 mg/day was reported to be effective in a double-blind crossover study in 24 nondepressed patients with chronic tension headaches ([Bendtsen and Jensen 2004](#)). Area under the curve (intensity × duration) for headache was significantly lower for mirtazapine than for placebo.

## Nausea

A case series of 20 patients with breast or gynecological cancer who were treated with mirtazapine demonstrated a significant reduction in symptoms of depression, anxiety, nausea, anorexia, and insomnia in 19 of the patients, as well as a lack of adverse drug interactions with oncology treatment regimens, including chemotherapy ([Thompson 2000](#)).

A 7-week open-label crossover trial of mirtazapine in 20 patients with cancer found significant improvements in mood, anxiety, insomnia, appetite, weight, and pain symptoms by study endpoint ([Theobald et al. 2002](#)).

It has been suggested that mirtazapine could prove to be a safe and effective adjunct to cancer chemotherapy

because of its ability to treat nausea via a 5-HT<sub>3</sub> receptor antagonism effect; insomnia, anorexia, and weight loss via H<sub>1</sub> receptor antagonism; symptoms of depression via enhanced 5-HT and noradrenergic transmission by way of  $\alpha_2$ , 5-HT<sub>2</sub>, and 5-HT<sub>3</sub> receptor blockade; and symptoms of anxiety via 5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptor antagonism ([Kast 2001](#)). A randomized, double-blind trial reported that the incidence of nausea and vomiting after spinal anesthesia with intrathecal morphine was significantly lower in orthopedic surgery patients who received preoperative mirtazapine (30 mg) than in those who received placebo ([Chang et al. 2010](#)).

A review of seven cases of pregnant patients with treatment-refractory hyperemesis gravidarum and symptoms of depression and anxiety concluded that treatment with mirtazapine produced resolution of symptoms without adverse effects on the newborns ([Saks 2001](#)).

## Vasomotor Symptoms

[Waldinger et al. \(2000\)](#) described four cases in which women (ages between 39 and 60 years) experienced a near-complete resolution of symptoms of hot flushes and perspiration within the first week of treatment with mirtazapine.

## Pediatric Depression and Anxiety

Mirtazapine has been assessed in several trials involving children or adolescents with major depressive disorder or

anxiety disorders. In one trial in 24 adolescents with major depressive disorder, patients responded well to mirtazapine, with no dropouts due to side effects ([Haapasalo-Pesu et al. 2004](#)). In another small open-label trial in 18 patients with social phobia, mirtazapine also demonstrated efficacy ([Mrakotsky et al. 2008](#)). Although there was a very high dropout rate, most of the discontinuations were not due to side effects.

## Pervasive Developmental Disorders

In an open-label study on the use of mirtazapine in 26 patients with DSM-IV pervasive developmental disorders, 35% of subjects demonstrated significant improvement on CGI scores with respect to symptoms of aggression, self-injury, irritability, hyperactivity, anxiety, depression, and insomnia ([Posey et al. 2001](#)).

## Depression in Alzheimer's Disease

[Raji and Brady \(2001\)](#) described three cases of patients with comorbid Alzheimer's dementia (Mini-Mental State Exam [MMSE] scores of 21/30, 11/30, and 18/30) and depressive symptomatology (including weight loss, insomnia, and anxiety) who were treated safely with mirtazapine. The patients demonstrated significant improvements in appetite, weight, sleep, mood, and energy level.

However, in a large-scale trial comparing sertraline (up to 150 mg/day), mirtazapine (up to 45 mg/day), and placebo in Alzheimer's disease patients with depression, there were no differences among the three groups in reduction of

depressive symptoms ([Banerjee et al. 2011](#)). Given these negative findings regarding benefit and the heightened risk of side effects from these drugs, the authors recommended that the current practice of prescribing antidepressants in this patient population be reconsidered.

## Add-On Therapy in Schizophrenia

The utility of mirtazapine in the treatment of the negative symptoms of schizophrenia has been examined in several studies. In a 6-week double-blind, randomized, placebo-controlled trial, the addition of mirtazapine to haloperidol in the treatment of schizophrenia produced statistically significant reductions in Positive and Negative Syndrome Scale (PANSS) scores, as well as in CGI-Severity and CGI-Improvement scores ([Berk et al. 2001](#)). In addition, PANSS negative symptom scores in this study were found to be reduced by 42% in the group of patients who received adjunctive mirtazapine compared with the group who received placebo ([Berk et al. 2001](#)). Furthermore, the improvement in negative symptoms was not correlated with Ham-D scores at study endpoint, suggesting that the effect of mirtazapine on diminution of negative symptoms in schizophrenia was not a result of improvement in mood symptoms ([Berk et al. 2001](#)).

In a subsequent study, [Berk et al. \(2009\)](#) compared mirtazapine (30 mg/day) with placebo add-on in schizophrenia patients being treated with atypical antipsychotics. Mirtazapine's effects on negative symptoms or cognition failed to separate from those of placebo.

Several positive studies have followed the mixed findings of Berk and colleagues. [Abbasi et al. \(2010\)](#) reported that

mirtazapine add-on at 30 mg/day was significantly more effective than placebo in reducing negative symptoms and total PANSS scores in schizophrenia patients being treated with risperidone. Similarly, [Cho et al. \(2011\)](#) noted that mirtazapine augmentation separated from placebo in improving negative symptoms and cognition in patients undergoing treatment with risperidone. Neuropsychological testing results likewise showed significantly greater improvement with mirtazapine. [Stenberg et al. \(2010\)](#) reported that patients who were not sufficiently improved on first-generation antipsychotics showed significantly greater improvement in cognition with mirtazapine than with placebo.

A meta-analysis examining the safety and efficacy of adjunctive antidepressants for cognitive impairment in schizophrenia included four studies of mirtazapine. In this investigation, statistically significant but minimal clinical effects were noted for all drugs ([Vernon et al. 2014](#)).

## Akathisia

[Poyurovsky et al. \(2003, 2006\)](#) conducted two double-blind, placebo-controlled studies of mirtazapine treatment of antipsychotic-induced akathisia in patients with schizophrenia. In the first study ([Poyurovsky et al. 2003](#)), mirtazapine 15 mg/day was compared with placebo in 26 patients. The drug was significantly superior to placebo. In the second study ([Poyurovsky et al. 2006](#)), mirtazapine 15 mg/day was compared with propranolol 80 mg/day or placebo in 90 patients. Both drugs separated from placebo, but propranolol was associated with clinically significant bradycardia and hypotension.

---

## Side Effects and Toxicology

---

In a double-blind, placebo-controlled study of outpatients with depression, the most commonly reported side effects associated with mirtazapine treatment were somnolence, increased appetite, and weight gain ([Claghorn and Lesem 1995](#)).

In a review of data from the clinical development program for mirtazapine, the only adverse effects that occurred at a higher incidence with mirtazapine versus placebo were excessive sedation, increased appetite, weight gain, and dry mouth ([Montgomery 1995](#)). The authors noted that these side effects were typically mild and transient in nature and that they diminished over time even when dosages were increased ([Montgomery 1995](#)).

Side effects typical of SSRIs, such as nausea, diarrhea, and sexual dysfunction, appear to occur less frequently in patients treated with mirtazapine ([Boyarsky et al. 1999](#); [Farah 1998](#); [Montgomery 1995](#); [Stimmel et al. 1997](#)).

Mirtazapine appears to be well tolerated in elderly patients. The side effects most commonly reported—including somnolence, increased appetite, weight gain, and dry mouth—are of the same type as those reported in younger adults ([Fawcett and Barkin 1998b](#); [Halikas 1995](#)). In a large study of 170,000 psychiatric inpatients in German-speaking countries, mirtazapine was found to be associated with significantly fewer cardiovascular adverse events compared with all other antidepressants (monoamine oxidase inhibitors, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and SSRIs) ([Spindelegger et al. 2014](#)).

Mirtazapine appears to have a very low propensity to cause clinically relevant laboratory abnormalities, such as transient elevations in liver enzymes (which occur in about 2% of patients) and severe neutropenia (in 0.1%) ([Claghorn and Lesem 1995](#); [Fawcett and Barkin 1998b](#); [Kent 2000](#); [Montgomery 1995](#)).

Mirtazapine appears to have no clinically significant effects on seizure threshold or on the cardiovascular system ([Claghorn and Lesem 1995](#); [Fawcett and Barkin 1998b](#); [Kent 2000](#); [Montgomery 1995](#)).

Of note, the noradrenergic effects of mirtazapine appear to be dose dependent and increase significantly at dosages >15 mg/day. Consistent with this pattern, the sedation associated with mirtazapine's affinity for H<sub>1</sub> receptors and typically experienced at dosages of ≤15 mg/day may be counteracted by enhancement of noradrenergic neurotransmission via increased dosages of ≥30 mg/day ([Claghorn and Lesem 1995](#); [Kent 2000](#)). It is likewise hypothesized that the risk of weight gain with mirtazapine is diminished at dosages ≥30 mg/day ([Barkin et al. 2000](#); [Fawcett and Barkin 1998b](#)). However, a recent meta-analysis indicated that mirtazapine was associated with considerable weight gain (average of 1.5 kg) in the randomized clinical trials ([Domecq et al. 2015](#)).

## Use During Pregnancy and Lactation

A study conducted across six countries ([Djulus et al. 2006](#)) assessed the risk associated with exposure to mirtazapine during pregnancy. Birth outcomes were examined for three groups: pregnant women taking mirtazapine, disease-matched pregnant women taking other antidepressants,

and pregnant women exposed to nonteratogens. There were approximately 100 patients per group. The rate of spontaneous abortions in the mirtazapine group (19%) was similar to that in the other antidepressant group (17%) and in the nonteratogen control group (11%). The rate of prematurity was significantly higher in the mirtazapine group (10%) versus the nonteratogen group (2%). The prematurity rate in the group taking other antidepressants was 7%. The rate of major malformations was not elevated in the mirtazapine group.

In a study of 8 women taking mirtazapine while breast feeding, concentrations of mirtazapine or desmethylmirtazapine were measured in milk and plasma ([Kristensen et al. 2007](#)). Low infant doses were observed, leading the authors to conclude that the drug is safe for lactating women who breast feed.

## Overdose

Mirtazapine appears to be safe in overdose. In one report ([Holzbach et al. 1998](#)), the cases of 2 patients who had overdosed with 30-50 times the average daily dose of mirtazapine were presented. In each case, the patient recovered fully and without any complications.

Symptoms reported in cases of mirtazapine overdose include disorientation, drowsiness, impaired memory, and tachycardia ([Fawcett and Barkin 1998b](#); [Kent 2000](#); [Montgomery 1995](#); [Stimmel et al. 1997](#)).

A review of 117 mirtazapine overdoses (average ingestion: 450 mg) in Scotland revealed the adverse consequences to be relatively mild ([Waring et al. 2007](#)).

Decreased consciousness was seen in 27% of subjects; 30% demonstrated tachycardia.

A more recent study of overdoses seen at six general hospitals in the United Kingdom between 2000 and 2006 indicated that mirtazapine was of intermediate toxicity between tricyclic antidepressants and venlafaxine, on the one hand, and SSRIs, on the other ([Hawton et al. 2010](#)). Another study of 239,000 patients in the United Kingdom reported that mirtazapine was significantly more likely than citalopram to be associated with suicide, attempted suicide, or self-harm; however, the number of events was low ([Coupland et al. 2015](#)). Trazodone and venlafaxine also were associated with more overdose events. That mirtazapine and trazodone—two sedating antidepressants often prescribed for depressed patients with comorbid sleep problems—were both noted to be associated with suicidal behavior raises the possibility that baseline insomnia, rather than specific drug effects, might explain at least some of the increased risk of suicide attempts.

---

## Drug-Drug Interactions

---

In vitro data suggest that mirtazapine is unlikely to have clinically significant effects on the metabolism of drugs by CYP enzymes ([Barkin et al. 2000](#); [Fawcett and Barkin 1998b](#); [Kent 2000](#)). Analyses of data from the clinical development program for mirtazapine and postmarketing surveillance reveal no clinically relevant drug-drug interactions from the concomitant use of medications such as opiates, anticonvulsants, analgesics, antihypertensives, diuretics, or nonsteroidal anti-inflammatory drugs (NSAIDs)

(Barkin et al. 2000; Fawcett and Barkin 1998b). However, few formal drug interaction studies involving mirtazapine have been conducted (Barkin et al. 2000; Fawcett and Barkin 1998b; Holm and Markham 1999). Of note, a study of elderly patients with depression allowed for patients to be on drugs that are CYP2D6 substrates (Schatzberg et al. 2002). In this study, no increase in side effects was observed in these patients compared with patients who were not taking CYP2D6 substrate agents (Schatzberg et al. 2002).

---

## Conclusion

---

Mirtazapine is derived from the piperazinoazepine class of compounds and, as such, is structurally unrelated to any other psychotropic medications. Mirtazapine also is unique as an antidepressant because of its 5-HT<sub>2</sub>, 5-HT<sub>3</sub>, and  $\alpha_2$  receptor antagonist pharmacodynamic profile, which results in enhancement of noradrenergic and serotonergic transmission. It is an antidepressant that has been shown to be efficacious and well tolerated in the treatment of depression, and there are indications that it may be effective in a number of other medical and psychiatric conditions. Moreover, mirtazapine may offer a more rapid amelioration of symptoms of depression and anxiety compared with other antidepressants. The most common side effects reported with mirtazapine are somnolence, increased appetite, weight gain, and dry mouth. It otherwise appears to be free of many of the adverse effects typical of the SSRIs, especially sexual dysfunction.

Furthermore, mirtazapine appears to be well tolerated and effective in the treatment of geriatric depression and to have benefit as an add-on agent in schizophrenia. In addition, mirtazapine is considered to be relatively safe in overdose, with case reports documenting complete and uncomplicated recovery following ingestion of up to 50 times the average daily dosage. Finally, mirtazapine appears to be devoid of clinically significant drug-drug interactions, although larger formal clinical trials are still needed to verify this.

# CHAPTER 18

## Bupropion

David V. Hamilton, M.D., M.A.

Anita H. Clayton, M.D.

---

### History and Discovery

---

Bupropion was discovered 50 years ago when investigators were searching for an antidepressant with a novel mechanism of action and safer side-effect profile compared with the antidepressants available at that time. Synthesized in 1966, this unique compound, different from the tricyclic antidepressants (TCAs) and the monoamine oxidase inhibitors (MAOIs), was found to have antidepressant activity in animal models that are predictive of antidepressant activity in humans ([Soroko and Maxwell 1983](#)).

Bupropion's mechanism of action is thought to be related to its dual inhibition of norepinephrine and dopamine reuptake and its lack of clinically significant serotonin reuptake inhibition ([Horst and Preskorn 1998](#); [Stahl et al.](#)

2004). Bupropion and selective serotonin reuptake inhibitors (SSRIs) appear to be equally efficacious in the treatment of major depressive disorder (Feighner et al. 1991). The sustained-release formulation of bupropion, approved in 1996, was also shown to be significantly better than placebo in preventing depression relapse (Weihs et al. 2002). Bupropion's tolerability is superior to that of the SSRIs, with less weight gain, less sedation, no withdrawal symptoms upon discontinuation, and minimal sexual side effects (Thase et al. 2005).

In addition to its demonstrated benefit in the treatment of major depressive disorder, bupropion has been found to be effective across a wide range of depressive conditions, subtypes, and comorbidities (Clayton 2007), including depression with concomitant anxiety, depression in the elderly, seasonal depression, and bipolar depression, and also as an augmentation agent in patients with insufficient response to SSRIs. Bupropion's efficacy in other conditions has also been shown in studies of smoking cessation, obesity, attention-deficit/hyperactivity disorder (ADHD), and DSM-IV (American Psychiatric Association 1994) hypoactive sexual desire disorder (HSDD). Overall, bupropion is a unique antidepressant with a broad therapeutic spectrum and a superior tolerability profile.

Bupropion first received U.S. Food and Drug Administration (FDA) approval in 1985 and was on the brink of release when a study by Horne et al. (1988) reported that 4 of 55 subjects with bulimia experienced seizures during treatment with the medication. Further research revealed that the risk of seizures increased with dosage, from a risk of 0.3%–0.4% at a dosage of 450 mg/day to a risk of almost 2% at a dosage of 600 mg/day. Bupropion was reintroduced in 1989 with a maximum recommended

dosage of 450 mg/day ([Davidson 1989](#)). The original immediate-release (IR) formulation of bupropion was dosed three times daily ([GlaxoSmithKline 2016a](#)). In an effort to improve tolerability and safety, a sustained-release (SR) formulation of bupropion, dosed twice daily, was subsequently introduced ([GlaxoSmithKline 2016b](#)), and a once-daily extended-release (XL) formulation became available in 2003 ([Valeant Pharmaceuticals North America 2014](#)).

---

## Structure-Activity Relations

---

Bupropion, 2-(tert-butylamino)-1-(3'-chlorophenyl)propan-1-one, is a monocyclic antidepressant and a member of the aminoketone group ([Figure 18-1](#)). It was designed as a simple chemical structure that in vivo would result in relatively innocuous metabolites ([Mehta 1983](#)). Chemically, bupropion is an organic base with a high degree of both water and lipid solubility, resulting in good systemic absorption. Its relatively benign side-effect profile in comparison with that of tricyclic and tetracyclic antidepressants is due to the absence of heterocyclic rings as well as other common functional groups ([Mehta 1983](#)).

---

## Pharmacological Profile

---

Bupropion inhibits the reuptake of dopamine and norepinephrine by acting as a nonselective inhibitor of the dopamine transporter (DAT) and the norepinephrine transporter (NET). Studies show that bupropion also acts as an antagonist to nicotinic acetylcholine (nACh) receptors. Bupropion does not inhibit monoamine oxidase A or B, nor are its effects mediated by serotonin ([Ascher et al. 1995](#)).

Studies have demonstrated that bupropion raises dopamine concentrations by causing a rapid and reversible increase in vesicular dopamine reuptake via cellular redistribution of the vesicular monoamine transporter 2 (VMAT2) protein. By increasing the presynaptic pool of dopamine available for release, the concentration of dopamine in the extracellular space is further augmented, adding to the therapeutic efficacy of this compound ([Dwoskin et al. 2006](#); [Rau et al. 2005](#)).

Although more is known about the dopaminergic effects of bupropion, interaction with the noradrenergic system also plays an important role in the drug's antidepressant activity. Bupropion is a weak competitive inhibitor of norepinephrine; in comparison with imipramine, it is 65 times less potent ([Ferris and Beaman 1983](#)). Research using various cellular expression systems has elucidated the ability of bupropion to interact with specific nACh receptors. Bupropion has been shown to work by noncompetitive inhibition of nACh receptors ([Dwoskin et al. 2006](#)). This action may partially contribute to bupropion's

efficacy not only as an antidepressant but also as an agent to facilitate tobacco cessation.

It has been noted that bupropion shares some structural and neurochemical properties with sympathomimetics and has a phenylethylamine skeleton similar to that of amphetamine. An early study by [Griffith et al. \(1983\)](#) comparing the effects of bupropion and amphetamine in individuals with a history of amphetamine abuse concluded that bupropion had little abuse potential in humans. However, recent reports have described cases in which bupropion was perceived as a psychostimulant by patients with a previous history of cocaine abuse ([Vento et al. 2013](#)). An 11-year review by [Lewis et al. \(2014\)](#) of data from the California Poison Control Center found that 3.6% of all calls to the center regarding bupropion were due to intentional insufflation in order to achieve a psychostimulant effect, with an average dose of 1,500 mg. [Hilliard et al. \(2013\)](#) reported that bupropion is especially valued as a stimulant of abuse in the incarcerated population. These preliminary data point to the need to continue to monitor bupropion users for potential abuse, especially in patient populations that are at increased risk of developing substance use disorders and in those patients with a history of stimulant use disorders.

## Pharmacokinetics and Disposition

---

Bupropion is rapidly absorbed in the gastrointestinal tract after oral administration ([Findlay et al. 1981](#); [Jefferson et al. 2005](#)). Absorption has been found to be close to 100%

([Schroeder 1983](#)). After first-pass metabolism, systemic bioavailability of the drug is decreased. Peak plasma levels occur within 2 hours for the IR preparation. As expected, absorption is prolonged for the SR and XL formulations, for which peak plasma concentrations occur at 3 and 5 hours, respectively ([Jefferson et al. 2005](#); [Schroeder 1983](#)). Food does not impair absorption, and protein binding ranges from 82% to 88%, which is not high enough to be of clinical importance ([Jefferson et al. 2005](#)). The elimination half-life for bupropion is 21 ( $\pm 9$ ) hours, and the half-life for hydroxybupropion, the major metabolite of bupropion, is close to 20 ( $\pm 5$ ) hours ([Clayton 2007](#); [Jefferson et al. 2005](#)). Steady state occurs in 7–10 days. Finally, excretion in the urine occurs with 0.5% of the drug unchanged ([Findlay et al. 1981](#); [Jefferson et al. 2005](#)).

Bupropion is extensively metabolized by the liver. The major metabolite, hydroxybupropion, is hydrolyzed by cytochrome P450 (CYP) 2B6 ([Hesse et al. 2000](#); [Kirchheiner et al. 2003](#)). The peak plasma concentration of hydroxybupropion at steady state is four- to sevenfold higher than that of bupropion. Although CYP2B6 is the primary isoenzyme involved in bupropion's metabolism, other isoforms, including 1A2, 2A6, 2C9, 2D6, 2E1, and 3A4, play a small role ([Hesse et al. 2000](#); [Kirchheiner et al. 2003](#)). Bupropion inhibits CYP2D6 and therefore may interfere with drugs that are metabolized by this enzyme, such as desipramine and nortriptyline ([Hesse et al. 2000](#); [Jefferson et al. 2005](#)). A recent study showed that increased levels of estradiol produce a 1.5- to 3-fold increase in CYP2B6 activity, making estradiol as strong an inducer as rifampin ([Dickmann and Isoherranen 2013](#)). Theoretically, this interaction could lead to decreased levels of bupropion and its active metabolite, with worsening therapeutic

outcomes in pregnancy (although such outcomes have not yet been demonstrated).

In examining the pharmacokinetics of bupropion in regard to gender, age, and smoking status, no significant effect has been found, and definitive results have been inconclusive ([Daviss et al. 2006](#); [Hsyu et al. 1997](#); [Jefferson et al. 2005](#)). One study in elderly patients found evidence for an extended half-life of bupropion and for accumulation of metabolites ([Sweet et al. 1995](#)). Because levels of bupropion and its metabolites have been found to be increased in populations with impaired renal and/or hepatic function relative to healthy control subjects ([DeVane et al. 1990](#); [Jefferson et al. 2005](#); [Worrall et al. 2004](#)), dosing should be initiated at lower levels in these patients. [Worrall et al. \(2004\)](#) showed that accumulation of two of the metabolites of bupropion—hydroxybupropion and threohydrobupropion—was significantly elevated in patients with end-stage renal disease compared with matched controls. Other studies found increased levels of both bupropion and hydroxybupropion in patients with hepatic dysfunction ([DeVane et al. 1990](#); [GlaxoSmithKline 2016a, 2016b](#); [Jefferson et al. 2005](#)). These results prompted the manufacturer to recommend that bupropion be used with caution in patients with mild to moderate liver disease and with extreme caution in patients with severe liver disease ([GlaxoSmithKline 2016a, 2016b](#)).

## Mechanism of Action

---

Despite considerable effort spent in elucidating bupropion's mechanism of action, what we know is limited. Preclinical

data indicate that bupropion does not bind to postsynaptic histamine,  $\alpha$ - or  $\beta$ -adrenergic, or serotonin receptors, nor does it inhibit monoamine oxidase ([Ascher et al. 1995](#); [Baldessarini 2001](#); [Fava et al. 2005](#); [Stahl et al. 2004](#)). Thus, among the myriad of antidepressants now available, bupropion is the only agent without substantial serotonergic activity ([Ascher et al. 1995](#); [Richelson 1996](#); [Stahl et al. 2004](#)).

Bupropion's three major metabolites—hydroxybupropion, threohydrobupropion, and erythrohydrobupropion—play a crucial role in its antidepressant activity (GlaxoSmithKline [2016a](#), [2016b](#)). In vitro studies have demonstrated that bupropion and its active metabolites inhibit both the NET and the DAT (described in [Fava et al. 2005](#)).

Although other antidepressants that affect NET receptors are thought to produce their effects by downregulation of postsynaptic noradrenergic receptors, bupropion differs in that it decreases the firing rate of neurons in the locus coeruleus in a dose-dependent manner (B.R. [Cooper et al. 1994](#); T.B. [Cooper et al. 1984](#)). Acute administration of bupropion not only decreases firing of brain-stem norepinephrine and dopamine neurons but also increases extracellular norepinephrine and dopamine concentrations in the nucleus accumbens ([Fava et al. 2005](#)). Furthermore, the efficacy of bupropion and hydroxybupropion has been shown to diminish in animal models when norepinephrine- or dopamine-blocking drugs are administered (B.R. [Cooper et al. 1980](#); [Dwoskin et al. 2006](#)).

---

## Indications and Efficacy

---

# Primary Indications

## Major Depressive Disorder

Bupropion's efficacy in the treatment of major depressive disorder (MDD) is supported by many clinical trials. The drug's three formulations are equally useful for this therapeutic indication ([Fabre et al. 1983](#); [Lineberry et al. 1999](#)). Comparison trials have demonstrated that bupropion is as effective as other classes of antidepressants, including TCAs and SSRIs ([Branconnier et al. 1983](#); [Clayton et al. 2006](#); [Coleman et al. 1999, 2001](#); [Croft et al. 1999](#); [Feighner et al. 1986](#); [Kavoussi et al. 1997](#); [Mendels et al. 1983](#); [Thase et al. 2005](#); [Weihs et al. 2000](#)). In comparisons with specific drugs, bupropion's efficacy in depression was found to be equal to that of fluoxetine ([Feighner et al. 1991](#)) and of trazodone ([Weisler et al. 1994](#)).

The development of bupropion SR launched several comparison studies with SSRIs, including fluoxetine, sertraline, and paroxetine. In most studies, the effective daily dosage of bupropion SR was between 300 mg and 400 mg. All studies demonstrated that bupropion's effectiveness in treating symptoms of depression was equal to that of SSRIs ([Coleman et al. 1999, 2001](#); [Croft et al. 1999](#); [Kavoussi et al. 1997](#); [Weihs et al. 2000](#)). In a meta-analysis of remission data from all existing bupropion SR versus SSRI comparative trials, [Thase et al. \(2005\)](#) found that remission rates were essentially the same for the two types of antidepressants. Although both bupropion SR and SSRIs were generally well tolerated, bupropion SR treatment was associated with lower rates of sexual dysfunction ([Thase et al. 2005](#)). Bupropion SR has also been shown to prevent

relapse of depressive symptoms in continuation treatment extending up to 1 year ([Weihs et al. 2002](#)).

The release of bupropion XL in 2003 also generated several comparison studies. In two 8-week placebo-controlled comparative trials with bupropion XL and escitalopram, pooled analysis confirmed equivalent efficacy of the two agents based on mean change in Hamilton Rating Scale for Depression (Ham-D; [Hamilton 1960](#)) score. Both antidepressants produced remission rates greater than the rate with placebo alone ([Clayton et al. 2006](#)). Other studies comparing bupropion XL with the serotonin-norepinephrine reuptake inhibitor (SNRI) venlafaxine XR demonstrated clinical equivalence for the two drugs in the treatment of depression. Notably, a study that used higher dosages of bupropion XL (300–450 mg/day) found statistically significantly higher remission rates for bupropion XL relative to venlafaxine XR ([Thase et al. 2006](#)). By contrast, two studies by Hewitt and colleagues found low dosages of venlafaxine XR (75–150 mg/day) to be superior to low dosages of bupropion XL (150–300 mg/day). In both studies, a flexible dosing schedule was employed; that is, patients were given the option of doubling the dosage at week 5 if their response was inadequate. Of note, in these studies bupropion XL was not superior to placebo ([Hewitt et al. 2009, 2010](#)).

Although bupropion has not been shown in a naturalistic setting to have better effectiveness than other antidepressant agents, specific neurocognitive markers may help steer the clinician toward the choice of bupropion for a specific patient. In a small-sample study, [Bruder et al. \(2014\)](#) found that performance on brief tests of word fluency and psychomotor speed predicted which patients would preferentially respond to bupropion monotherapy

relative to either SSRI monotherapy or SSRI + bupropion combination therapy. However, other small (but statistically significant) studies have suggested that SSRIs may be more effective than bupropion in decreasing suicidal thoughts during the initial weeks of pharmacotherapy in high-risk patients ([Grunebaum et al. 2013](#)).

Studies have shown bupropion to be efficacious in the treatment of MDD not only as monotherapy but also as an augmenting agent with SSRIs or SNRIs ([Bodkin et al. 1997](#); [DeBattista et al. 2003](#); [Fava et al. 2003](#); [Ferguson et al. 1994](#); [Lam et al. 2004](#); [Rush et al. 2006](#); [Spier 1998](#); [Stern et al. 1983](#); [Trivedi et al. 2006](#)). Whereas the “triple monoamine approach” (i.e., using an SSRI with bupropion in order to block reuptake of serotonin, dopamine, and norepinephrine) is often a useful strategy, [Stewart et al. \(2014\)](#) demonstrated that the addition of bupropion XL at a relatively high dosage (i.e., 450 mg/day) to a similarly high dosage of escitalopram (i.e., 40 mg/day) increased neither the speed of recovery nor the likelihood of recovery from a major depressive episode. [Nasr et al. \(2014\)](#) compared the outcomes of patients who received either aripiprazole or bupropion as an adjunct to SSRI treatment. Although no overall differences were found between the two augmenting agents, bupropion was significantly more helpful in treating poor energy and motivation, whereas aripiprazole proved superior in reducing suicidal ideation. This finding suggests that a careful symptom inventory is the best guide in selecting an augmenting agent.

The Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) study was the largest protocol-driven study of MDD ever undertaken, with an initial study population of 4,041. A retrospective analysis of this study directly addressed the question of which next-step strategy

—medication augmentation or medication switching—yields the best outcome for patients whose symptoms have not improved after an adequate trial of antidepressant monotherapy ([Gaynes et al. 2012](#)). Findings specific to bupropion suggested that patients who completed an initial 12-week period of citalopram treatment without experiencing complete symptom remission received more benefit from augmenting citalopram with bupropion than from discontinuing citalopram and switching to bupropion.

**Depression in the elderly.** Depression in the elderly is often underdiagnosed and may go untreated. Older individuals tend to describe nonspecific somatic symptoms, such as insomnia, anorexia, and low energy, instead of reporting depressed mood ([Birrer and Vemuri 2004](#)). Bupropion has been found to be an effective antidepressant in elderly patients ([Birrer and Vemuri 2004](#); [Branconnier et al. 1983](#); [Weihs et al. 2000](#)). A study comparing bupropion SR and the SSRI paroxetine noted that although both agents were effective in treating depression, bupropion SR had a more favorable side-effect profile ([Weihs et al. 2000](#)). Like bupropion SR, bupropion XL has shown efficacy in the treatment of depression in elderly individuals ([Clayton 2007](#)). However, a study examining whether gender- or age-related differences in efficacy exist between SSRIs and bupropion for treatment of depressive symptoms, anxious/somatic symptoms, and insomnia found SSRIs and bupropion to be equally effective in treating these symptoms across all age and gender groups ([Papakostas et al. 2007](#)).

**Depression with decreased energy, interest, and pleasure.** Bupropion XL has been studied

specifically in depressed patients with a retarded/anergic symptom profile. [Jefferson et al. \(2006\)](#) showed that bupropion XL was more effective than placebo in depressed patients with decreased energy, pleasure, and interest. Bupropion's unique norepinephrine-dopamine reuptake inhibitor (NDRI) mechanism of action may play a role in its effectiveness in treating these symptoms ([Jefferson et al. 2006](#)).

**Anxiety symptoms in depression.** Studies have demonstrated the effectiveness of bupropion dosages of 300–400 mg/day in reducing symptoms of anxiety ([Fabre et al. 1983](#)). Moreover, bupropion and SSRIs appear to be equally effective in reducing symptoms of anxiety associated with MDD in both the general population and the elderly ([Feighner et al. 1991](#); [Weihs et al. 2000](#)). In 2001, Trivedi et al. published results of a study examining the effects of bupropion SR versus sertraline on anxiety in depressed patients, reporting that both bupropion SR and sertraline were superior to placebo in allaying depressive symptoms; however, treatment of anxious symptoms did not significantly differ from placebo for either active medication. The study concluded that bupropion and SSRIs were comparable in their antidepressant and anxiolytic effects in patients with MDD. Neither was favored for more specific management of anxiety ([Trivedi et al. 2001](#)). A meta-analysis comparing the efficacy of bupropion and SSRIs for treatment of anxious symptoms in MDD concluded that both classes of medication led to a similar degree of improvement in anxiety symptoms, with no significant difference in the severity of residual anxiety symptoms ([Papakostas et al. 2008](#)).

**Bipolar depression.** A small number of early studies demonstrated the advantages of bupropion in the treatment of depression in bipolar disorder ([Haykal and Akiskal 1990](#); [Shopsin 1983](#); [Wright et al. 1985](#)). Although these investigations yielded positive results, they were limited by small numbers of subjects and lack of placebo control. Several trials have examined the risk of treatment-emergent mania with adjunctive use of bupropion in bipolar disorder. Although there appeared to be a lower risk of mania with bupropion and SSRIs than with the SNRI venlafaxine, findings regarding bupropion's efficacy in treating depressive symptoms in bipolar disorder were mixed ([Leverich et al. 2006](#); [Post et al. 2006](#); [Sachs et al. 2007](#)).

## **Prevention of Seasonal Major Depressive Episodes**

In 2006, bupropion XL ([Valeant Pharmaceuticals North America 2014](#)) became the first medication—and is still the only medication—to receive a labeled indication for the preventive treatment of seasonal depressive symptoms. A study published in 1992 initially suggested bupropion's efficacy as treatment for winter depression ([Dilsaver et al. 1992](#)). In 2005, Modell et al. published results of three prospective randomized, placebo-controlled prevention trials involving 1,042 outpatients with a diagnosis of seasonal major depressive episodes. Patients received 150–300 mg/day of bupropion XL or placebo in autumn while they were still well. Bupropion XL reduced the frequency of emergence of winter depression by 44% and protected against the recurrence of seasonal major depressive episodes. Furthermore, there was no noticeable increase in

major depressive episodes following discontinuation of bupropion in the springtime ([Modell et al. 2005](#)).

## Smoking Cessation

In 1997, bupropion SR received FDA approval for use as a smoking-cessation aid under the trade name Zyban (GlaxoSmithKline [2015](#)). The beneficial effect of bupropion on smoking cessation was first noted when researchers observed unplanned suspension of smoking in depressed subjects who were being treated with bupropion (reviewed in [Hudziak and Rettew 2004](#)). In a double-blind, placebo-controlled trial of bupropion SR therapy for smoking cessation ([Hurt et al. 1997](#)), 615 subjects received bupropion SR at dosages of 100, 150, or 300 mg/day for 7 weeks, with a target quit date of 1 week after beginning treatment. Brief counseling was also provided. Rates of smoking cessation at the end of 7 weeks were 29% for the 100-mg/day group, 39% for the 150-mg/day group, and 44% for the 300-mg/day group, versus 10% for placebo. At 1 year, rates for the three bupropion dosage groups were 20%, 23%, and 23%, respectively, compared with 12% for the placebo group.

Studies examining the long-term efficacy of bupropion SR for smoking relapse prevention have reported mixed findings. [Hays et al. \(2001\)](#) showed that subjects who had successfully stopped smoking for 7 weeks with bupropion treatment had a significant delay in smoking relapse with continued bupropion SR therapy compared with placebo. By contrast, a trial looking specifically at extended treatment with bupropion SR for smoking cessation reported that bupropion SR did not surpass placebo in efficacy ([Killen et al. 2006](#)). However, a meta-analysis of randomized controlled trials of pharmacotherapies for

smoking cessation subsequently confirmed the efficacy of bupropion in promoting smoking abstinence ([Eisenberg et al. 2008](#)).

Although more work needs to be done in the areas of relapse prevention and long-term abstinence, it appears evident that bupropion SR is helpful in smoking cessation. Recommended dosing is 150 mg/day for 3 days, increasing to 150 mg two times a day for 7–12 weeks, with patients setting a quit date of 1–2 weeks after treatment has been initiated. In 2003, Ferry and Johnston published a 5-year review of the accumulated efficacy and safety data for bupropion SR since its 1997 approval for smoking cessation. A benefit-risk analysis assuming a 30% 1-year quit rate concluded that for every 10,000 smokers treated with bupropion SR, 19 lives are saved and 86 cases of smoking-attributed morbidity are avoided, whereas the risk of a serious adverse effect from treatment is 0.22% ([Ferry and Johnston 2003](#)). Recent data have confirmed that bupropion evidences no increased risk of self-harm, suicide, or depression compared with either varenicline or nicotine replacement therapy ([Thomas et al. 2013](#)).

## **Obesity**

Unlike other classes of antidepressants, bupropion is well known for its lack of association with weight gain. Alternatively, mild, acute weight loss has been noted in many clinical trials. To further investigate this observation, [Gadde et al. \(2001\)](#) conducted a randomized, placebo-controlled trial investigating the tolerability and efficacy of bupropion (100–400 mg/day) for weight loss in 50 obese women. All subjects kept a food journal and were placed on a 1,600 kcal/day diet. At 8 weeks, subjects receiving bupropion had achieved greater weight loss compared with

those on placebo. At 24 weeks, responders to bupropion had lost an average of 13% of their baseline body weight ([Gadde et al. 2001](#)). Following this initial study of bupropion for weight loss, two larger studies confirmed these results ([Anderson et al. 2002](#); [Jain et al. 2002](#)).

In 2013, the FDA approved Contrave ([Orexigen Therapeutics 2014](#)), a bupropion/naltrexone combination, for the treatment of patients who are obese (defined as body mass index [BMI]  $\geq 30$  kg/m<sup>2</sup>) or overweight (defined as BMI  $\geq 27$  kg/m<sup>2</sup>) and have at least one cardiovascular risk factor ([Apovian et al. 2013](#)). FDA approval followed studies showing that bupropion/naltrexone combination therapy led to reductions in total and visceral adiposity ([Smith et al. 2013](#)). A drug safety evaluation of bupropion/naltrexone concluded that it led to greater weight loss compared with two other medications FDA approved for the treatment of obesity, orlistat and lorcaserin, but less weight loss compared with topiramate/phentermine combination therapy ([Verpeut and Bello 2014](#)). Furthermore, a study using functional magnetic resonance imaging demonstrated decreased reactivity to food cues following a course of bupropion/naltrexone therapy ([Wang et al. 2014](#)).

## Other Uses

### **Attention-Deficit/Hyperactivity Disorder**

Currently there is no FDA indication for bupropion's use in ADHD, although studies have demonstrated that it may be helpful in treating symptoms of ADHD in both children and adults ([Conners et al. 1996](#); [Simeon et al. 1986](#)). Clinical trials in children with ADHD have shown bupropion to be a

safe and effective alternative for treatment of this disorder (Conners et al. 1996). A comparison trial of bupropion and methylphenidate found that both drugs were effective in the treatment of ADHD and had similar efficacy (Barrickman et al. 1995). Bupropion has also been studied in adults with ADHD and has demonstrated statistically significant symptom improvement in this population (Wilens et al. 2001). In a meta-analysis by Peterson et al. (2008), long-acting forms of bupropion appeared to exhibit similar clinical effectiveness compared with long-acting stimulants in adults. An open trial by Riggs et al. (1998) suggested that bupropion may also be useful for the treatment of ADHD in adolescents with comorbid conduct disorder and substance use disorders. A recent large review of meta-analyses to date (Moriyama et al. 2013) concluded that bupropion therapy is more effective than placebo but less effective than stimulant therapy in the treatment of ADHD.

## **Sexual Dysfunction**

Bupropion has been studied as an antidote to SSRI-induced sexual dysfunction. A placebo-controlled comparative trial of bupropion SR treatment in 42 patients with SSRI-induced sexual dysfunction concluded that bupropion SR improved both the desire to engage in sexual activity and the frequency of engaging in sexual activity relative to placebo (Clayton et al. 2004). Safarinejad et al. (2010) demonstrated bupropion's efficacy in reversing SSRI-induced sexual dysfunction in men.

Segraves et al. (2001) found that bupropion may be helpful in the treatment of DSM-IV-TR HSDD. Subsequently, a double-blind, placebo-controlled trial supported this finding and also revealed increases in sexual arousal, orgasm completion, and sexual satisfaction in women with

DSM-IV-TR HSDD who received bupropion ([Segraves et al. 2004](#)). Another study of bupropion SR treatment of patients with SSRI-induced sexual dysfunction found that bupropion improved the desire to engage in sexual activity and increased the frequency of engaging in sexual activity ([Clayton et al. 2004](#)). Additional studies have also demonstrated that bupropion may be helpful for treating sexual disorders in both men and women ([Modell et al. 2000](#)). In a review of nontestosterone treatment options available for HSDD, [Lodise \(2013, p. 411\)](#) concluded that “bupropion is the primary pharmacologic agent that has shown positive results.”

## **Amphetamine Use Disorder**

Earlier in this chapter we discussed a burgeoning set of data pointing to the possibility that bupropion may be an emerging drug of abuse. Bupropion has been shown in vitro to increase dopamine uptake in the reward pathways in the brain, the very pathways whose function is deregulated or destroyed by chronic amphetamine abuse ([Simmler et al. 2013](#)). On the basis of its unique pharmacodynamics, bupropion is now being investigated as a possible treatment for stimulant use disorders, although results thus far have been mixed. In a review of randomized controlled trials, [Brensilver et al. \(2013\)](#) concluded that bupropion had not “produced an unambiguous, replicable signal of efficacy” in reducing stimulant use.

---

## **Side Effects and Toxicology**

---

Evidence from thousands of clinical trials and millions of patient exposures confirms that bupropion is a safe and generally well-tolerated medication across populations. Because of bupropion's unique mechanism of action and structure, its reported side effects are somewhat different from those of other antidepressants.

In a series of large randomized, placebo-controlled multicenter trials evaluating the safety of bupropion SR in the treatment of depressed outpatients, [Settle et al. \(1999\)](#) found that the most commonly reported adverse effects (occurring in >5% of subjects) were headache, dry mouth, nausea, insomnia, constipation, and dizziness. Only three of these—dry mouth, nausea, and insomnia—occurred at higher rates in patients taking bupropion SR than in those receiving placebo. The rate of discontinuation due to adverse effects was low: 7% for bupropion SR, compared with 4% for placebo. Rash, nausea, agitation, and migraine were the most common adverse effects leading to discontinuation ([Settle et al. 1999](#)). Similarly favorable safety and tolerability findings were reported for continuation-phase bupropion SR treatment in a longer-term (up to 44 weeks) relapse prevention trial ([Weihs et al. 2002](#)).

The side-effect profile of bupropion XL is similar to that of the other bupropion formulations and compares favorably with that of other controlled-release antidepressants. Compared with venlafaxine XR, bupropion XL was found to be associated with lower rates of dry mouth, nausea, diarrhea, somnolence, sedation, and yawning. These data indicate that bupropion XL does not appear to cause somnolence ([Clayton et al. 2006](#)). A review by [Fava et al. \(2005\)](#) also concluded that bupropion produces much less somnolence compared with SSRIs. Moreover, insomnia,

thought to be a particular side effect of bupropion, in fact occurs at rates similar to those seen with SSRIs ([Fava et al. 2005](#)).

Less common but potentially harmful adverse effects associated with bupropion include allergic reactions, seizures, and vital-sign changes. Allergic reactions, including rash, arthralgias, fever, and serum sickness-like reactions, have all been reported ([McCollom et al. 2000](#); [Tripathi and Greenberger 1999](#)). In light of these data, it is important to fully evaluate any reports of previous hypersensitivity before prescribing bupropion.

Screening for a history of seizure disorder or other organic brain disease should be performed before commencing a trial of bupropion. Seizure has been reported at a rate of 0.1% at dosages up to 300 mg/day with bupropion SR, with a dose-related effect ([Dunner et al. 1998](#)). This rate is similar to rates observed with other newer antidepressants, such as SSRIs and mirtazapine, but is lower than rates associated with therapeutic dosages of TCAs ([Montgomery 2005](#)).

Although cases of spontaneous hypertension with bupropion therapy have been reported, clinical trials across the approved dosage range have shown minimal changes in heart rate and blood pressure, even among patients with hypertension ([Jorenby et al. 1999](#); [Settle et al. 1999](#); [Thase et al. 2008](#)). In a smoking cessation study, patients receiving combination treatment with bupropion SR and a nicotine patch had a higher incidence of new or worsening hypertension compared with patients receiving either treatment alone or placebo ([Jorenby et al. 1999](#)). [Thase et al. \(2008\)](#) conducted a dose-response study to evaluate the potential of bupropion to elevate blood pressure. Bupropion SR dosages of 150–400 mg/day were administered to 296

nondepressed volunteers with mild hypertension. Findings indicated that bupropion SR did not separate from placebo on blood pressure changes. However, clinicians should be aware that elevated blood pressure is a possibility with bupropion therapy and should monitor patients accordingly.

Many agents used to treat depression have been associated with weight gain. This effect is thought to be associated with affinity for the H<sub>1</sub> histamine receptor, which is not a factor with bupropion. In fact, mild weight loss over time, rather than weight gain, has been reported with bupropion treatment ([Harto-Truax et al. 1983](#)). Studies have shown bupropion XL to be associated with weight loss of 0.1–1.1 kg in the short term, compared with placebo, which was associated with a small gain of 0.1–0.8 kg ([Jefferson et al. 2006](#); [Modell et al. 2005](#); [Thase et al. 2006](#)). In a longer-term depression relapse prevention study, [Croft et al. \(2002\)](#) observed that patients with higher BMIs at baseline experienced greater weight loss with bupropion XL than did patients with lower baseline BMIs.

Overall, at approved dosages, bupropion is a safe medication for depression in most populations and has an excellent tolerability profile. However, high blood levels of bupropion can be fatal. Serious medical consequences, such as hypertension, acidosis, sinus tachycardia, seizures, cardiotoxicity with QRS widening, and even death, have been reported with overdoses of bupropion ([Bhattacharjee et al. 2001](#); [Curry et al. 2005](#); [Shrier et al. 2000](#)).

On initiation of bupropion therapy, it is usually not necessary to obtain routine laboratory evaluations, although cases of elevated serum transaminase ([Oslin and Duffy 1993](#)) and rare cases of hepatitis ([Hu et al. 2000](#)) have been reported. Other unexpected changes in laboratory values have also occurred with bupropion

therapy and include false-positive results for urine amphetamine screening ([Weintraub and Linder 2000](#)).

Unfortunately, few data are available on the safety of bupropion in pregnancy. In a study by [Cole et al. \(2007\)](#), bupropion exposure in the first trimester was not associated with teratogenic effects. However, as previously described (see “Pharmacokinetics and Disposition” earlier in this chapter), the rapid increase in estradiol levels that occurs during pregnancy leads to strong induction of the CYP2B6 isoenzyme, the substrate primarily responsible for metabolizing bupropion ([Dickmann and Isoherranen 2013](#)). Further studies, with collection of hydroxybupropion levels, are needed to establish bupropion’s therapeutic effectiveness and safety in pregnant women.

## Drug-Drug Interactions

---

As discussed earlier, the main enzyme responsible for the metabolism of bupropion is CYP2B6. Competitive inhibition of metabolism can occur with other drugs processed by this enzyme, such as paroxetine, sertraline, diazepam, clonazepam, clopidogrel, ritonavir, and efavirenz ([Hesse et al. 2000](#); [Jefferson et al. 2005](#)). A study examining the effects of concurrent use of lopinavir/ritonavir on bupropion pharmacokinetics in 12 healthy subjects found that maximum plasma concentrations of bupropion and hydroxybupropion decreased by 57% and 31%, respectively ([Hogeland et al. 2007](#)).

Bupropion and its major metabolite hydroxybupropion are also inhibitors of CYP2D6, an enzyme that plays a role in the metabolism of several classes of medications,

including antidepressants, antipsychotics,  $\beta$ -blockers, and antiarrhythmic agents (Wilkinson 2005). Studies of the effects of bupropion on CYP2D6 activity are limited, but results of those conducted suggest that bupropion may increase blood levels of drugs metabolized by CYP2D6, such as desipramine and venlafaxine ([Jefferson et al. 2005](#); [Kennedy et al. 2002](#)). An 8-week open-label study of bupropion SR coadministered with venlafaxine, paroxetine, or fluoxetine found inhibition of venlafaxine metabolism and higher concentrations of venlafaxine. No significant interaction effects from bupropion were found for paroxetine or fluoxetine ([Kennedy et al. 2002](#)). Other agents known to induce various metabolic pathways have also been shown to affect the metabolism of bupropion. Carbamazepine, which induces CYP2B6, 3A4, and 1A2 activity, has been shown to decrease bupropion concentrations but increase hydroxybupropion concentrations ([Ketter et al. 1995](#)).

Bupropion should be used with caution in combination with other psychotropic agents that can lower the seizure threshold, such as tramadol, certain antidepressants, and antipsychotics ([Delanty et al. 1998](#); [Gardner et al. 2000](#)). It should also be used with caution in patients who abuse alcohol, because this population may have a higher risk of seizures ([Dunner et al. 1998](#)). In addition, because bupropion increases dopamine reuptake, additive effects with other dopaminergic agents (e.g., levodopa) are a possibility ([Goetz et al. 1984](#)).

## Conclusion

---

Bupropion is unique among the newer antidepressants in that it functions as a dopamine and norepinephrine reuptake inhibitor and as an antagonist of nACh receptors. Because bupropion has very little serotonergic activity, its side-effect profile differs markedly from that of other first-line agents, providing a treatment alternative for patients who cannot tolerate or who do not respond to SSRIs. Although its current FDA-approved indications are limited to the treatment of MDD, tobacco use disorder, and obesity and the prevention of seasonal major depressive episodes, bupropion has also demonstrated utility in child and adult ADHD and in sexual disorders. For targeted treatment of depression characterized by decreased energy and interest, depression with concomitant anxiety, and bipolar depression, bupropion may be particularly beneficial. Bupropion may also be used to augment other antidepressants in the treatment of MDD and to reverse SSRI-induced side effects. Greater tolerability, including low risk of weight gain, minimal sedation, and few sexual side effects, adds to bupropion's value as an effective antidepressant.

# CHAPTER 19

## Venlafaxine and Desvenlafaxine

Michael E. Thase, M.D.

---

### History and Discovery

---

Venlafaxine was developed as the first selective serotonin-norepinephrine reuptake inhibitor (SNRI) in the late 1980s and early 1990s ([Bolden-Watson and Richelson 1993](#); [Muth et al. 1986](#)). Several early randomized controlled trials (RCTs) confirmed that venlafaxine had antidepressant effects comparable to those of tricyclic antidepressants (TCAs), with fewer side effects attributable to anticholinergic and antihistaminergic activity (see, e.g., [Einarson et al. 1999](#)). An immediate-release (IR) form of venlafaxine was approved by the U.S. Food and Drug Administration (FDA) for the treatment of major depressive disorder (MDD) in 1994, and the extended-release (XR) formulation was introduced in 1997. Made available after several widely prescribed newer-generation

antidepressants (e.g., fluoxetine, sertraline, paroxetine), venlafaxine became one of the leading alternatives for patients who do not respond to selective serotonin reuptake inhibitors (SSRIs).

*O*-Desmethylvenlafaxine (ODV), the primary active metabolite of venlafaxine, is also classified as an SNRI. An extended-release formulation of ODV was developed and tested, and in 2008 desvenlafaxine succinate (DVS) received FDA approval for the treatment of MDD. Compared with venlafaxine, desvenlafaxine has somewhat greater potency for blockade of the norepinephrine transporter, and the succinate formulation has substantially greater bioavailability ([Deecher et al. 2006](#)).

---

## Structure-Activity Relations and Pharmacological Profile

---

Venlafaxine and desvenlafaxine are bicyclic phenylethylamine compounds and are structurally and chemically unrelated to all other available antidepressants and anxiolytics ([Figure 19-1](#)). Venlafaxine and desvenlafaxine inhibit the neuronal reuptake of serotonin (5-HT) and norepinephrine in both in vitro and ex vivo experimental paradigms ([Bolden-Watson and Richelson 1993](#); [Muth et al. 1986](#); [Owens et al. 1997, 2008](#)). Neither drug inhibits monoamine oxidase or has meaningful affinity for muscarinic, cholinergic, histaminergic H<sub>1</sub>, or  $\alpha$ -adrenergic receptors ([Bolden-Watson and Richelson 1993](#); [Muth et al. 1986](#)).

## Pharmacokinetics and Disposition

---

Venlafaxine and desvenlafaxine are well absorbed after oral ingestion and undergo extensive first-pass hepatic metabolism. ODV is the only active metabolite of venlafaxine, and ODV (desvenlafaxine) itself has no active metabolites. Following ingestion of venlafaxine IR, peak plasma concentrations are achieved within 2 hours for venlafaxine and within 3 hours for ODV ([Troy et al. 1995](#)). Venlafaxine XR is absorbed more slowly than the IR formulation (peak plasma concentrations are achieved within 5.5 hours for venlafaxine and within 9 hours for ODV), resulting in lower peak and higher trough plasma concentrations. Steady-state plasma concentrations of both venlafaxine and ODV are reached within 3–4 days of therapy. For extensive (i.e., normal) metabolizers, ODV accounts for at least 70% of the total drug concentration at steady state ([Klamerus et al. 1992](#)). Venlafaxine and

desvenlafaxine exhibit linear kinetics across clinically relevant dosages (i.e., 50–450 mg/day) ([Klamerus et al. 1992](#)). Both drugs are minimally bound to plasma albumin, and both are primarily eliminated by the kidneys ([Howell et al. 1993](#)). Clearance of ODV (half-life=10 hours) is slower than that of venlafaxine (half-life=4 hours).

The recommended starting dosage of venlafaxine is 75 mg/day (taken either in divided doses [IR] or once daily [XR]), which is the minimum effective dosage. A lower starting dosage (37.5 mg/day) is often used in older patients or those who have a history of tolerability problems. The maximum approved dosages for the IR and XR formulations are 375 mg/day and 225 mg/day, respectively. The recommended starting dosage of desvenlafaxine is 50 mg/day, which is also the minimum effective dosage; 100 mg/day is the maximum approved dosage. Lower dosages of both drugs are recommended for patients with renal insufficiency; lower dosages of venlafaxine are also recommended for patients with liver disease.

Venlafaxine shows a dose-response relationship for efficacy in MDD ([Kelsey 1996](#); [Khan et al. 1998](#); [Rudolph et al. 1998](#); [Thase et al. 2006](#)). Whereas the original form of venlafaxine was approved for treatment at dosages of up to 375 mg/day given in divided doses, the recommended maximum daily dosage of the once-daily XR formulation was “capped” at 225 mg.

Desvenlafaxine (administered as DVS) does not exhibit a positive dose-response curve for efficacy in MDD: drug-versus-placebo differences for 50 mg/day are as large as those observed for higher dosages ([Thase et al. 2009](#)). It has not been determined whether patients who do not respond to 50 mg/day might benefit from upward titration.

As we discuss later (see “Side Effects and Toxicology” section), there is a negative dose-response curve for tolerability, with any potential for added benefit at dosages above 100 mg/day offset by increased attrition due to intolerable side effects.

---

## Mechanism of Action

---

Venlafaxine and desvenlafaxine are potent inhibitors of 5-HT reuptake at minimum therapeutic dosages; inhibition of norepinephrine reuptake is lower at these dosages ([Bolden-Watson and Richelson 1993](#); [Deecher et al. 2006](#); [Owens et al. 2008](#); [Vaishnavi et al. 2004](#)). Studies using positron emission tomography (PET) to estimate receptor occupancy demonstrate that the minimum effective total daily dosage of venlafaxine (75 mg) yields about 80% occupancy of the 5-HT transporter ([Voineskos et al. 2007](#)). It has long been thought that the ascending dose-response relationship of venlafaxine is linked to a dose-dependent increase in norepinephrine transporter (NET) occupancy ([Kelsey 1996](#); [Thase and Sloan 2006](#)). Although some experimental ([Harvey et al. 2000](#)) and clinical ([Davidson et al. 2005](#); [Entsuah and Gao 2002](#); [Rudolph et al. 1998](#); [Thase 1998](#); [Thase et al. 2006](#)) data support this hypothesis, significant effects on autonomic measures of noradrenergic function are evident in healthy volunteers at “5-HT selective” dosages (i.e., 37.5 and 75 mg/day) of venlafaxine ([Bitsios et al. 1999](#); [Siepmann et al. 2007](#)). To date, PET studies of NET occupancy in depressed patients receiving venlafaxine have not been conducted. Results of one small PET study in primates suggested that in vivo NET occupancy of SNRIs is

greater than would be predicted from in vitro studies ([Takano et al. 2013](#)). There is no consensus about the optimal degree of NET inhibition during SNRI therapy.

---

## Indications and Efficacy

---

Venlafaxine is approved by the FDA for the treatment of MDD, generalized anxiety disorder (GAD), social anxiety disorder, and panic disorder. Desvenlafaxine is approved only for the treatment of MDD.

### Major Depressive Disorder

Venlafaxine's antidepressant efficacy at dosages ranging from 75 mg/day to 375 mg/day was established in a large number of RCTs (see [Thase and Sloan 2006](#) for a review). Meta-analyses of studies using active comparators concluded that venlafaxine is, at the least, one of the more effective newer-generation antidepressants ([Cipriani et al. 2009](#); [Nemeroff et al. 2008](#); [Schueler et al. 2011](#); [Smith et al. 2002](#); [Thase et al. 2001](#)). Evidence of venlafaxine's superiority over the SSRIs as a class is largely dependent on the high proportion of early studies using fluoxetine ([Cipriani et al. 2009](#); [Nemeroff et al. 2008](#)), and there is no evidence that venlafaxine is more effective than certain other members of the SSRI class, such as sertraline ([Cipriani et al. 2009](#)) and escitalopram ([Kennedy et al. 2009](#)).

The antidepressant efficacy of desvenlafaxine versus placebo was established at dosages ranging from 50 mg/day to 400 mg/day ([Kornstein et al. 2014](#); [Thase et al.](#)

2009). Only a handful of studies have compared desvenlafaxine with other active antidepressants, and there was no evidence for its greater efficacy. A meta-analysis of studies of desvenlafaxine at approved dosages (50–100 mg/day) concluded that its efficacy was similar to that of venlafaxine XR at comparable dosages (i.e., 75–225 mg/day) (Coleman et al. 2012).

With respect to other newer antidepressants, venlafaxine has been compared with mirtazapine (Benkert et al. 2006; Guelfi et al. 2001), bupropion (Hewett et al. 2010; Thase et al. 2006), duloxetine (Perahia et al. 2008), agomelatine (Kennedy et al. 2008), and vortioxetine (Alvarez et al. 2012; Wang et al. 2015). Overall, the results of these studies do not support the hypothesis that venlafaxine routinely conveys an efficacy advantage over other non-SSRI options. Furthermore, the results of these studies suggest that the various non-SSRI antidepressants may offer certain tolerability advantages over venlafaxine. For example, in comparison with venlafaxine, mirtazapine and agomelatine were more effective in insomnia, agomelatine and bupropion caused less treatment-emergent sexual dysfunction, and vortioxetine produced fewer noradrenergically mediated side effects (e.g., light-headedness) (Wang et al. 2015).

Neither venlafaxine nor desvenlafaxine has established efficacy in the adjunctive treatment of bipolar depression. In two comparison studies that enrolled patients with bipolar I depression who were being treated with mood stabilizers, adjunctive therapy with venlafaxine was associated with somewhat higher rates of treatment-emergent affective switches in comparison with adjunctive paroxetine (Vieta et al. 2002) and in comparison with adjunctive sertraline or bupropion (Post et al. 2006).

Interestingly, several studies comparing venlafaxine and lithium as monotherapy in outpatients with bipolar II depression ([Amsterdam and Shults 2008](#); [Amsterdam et al. 2016](#)) found significant advantages for the SNRI, with no increased risk of treatment-emergent affective shifts. Although it is difficult to reconcile these discrepancies, these results do suggest that a subset of patients within the broader bipolar spectrum can be treated safely and effectively with venlafaxine.

In an era in which most depressed patients are first treated with an SSRI, venlafaxine has for more than two decades been one of the preferred second-line choices for patients who do not respond to SSRI treatment ([Thase et al. 2000](#)). A meta-analysis of randomized trials of patients with SSRI-resistant depression comparing venlafaxine with other second-line antidepressants confirmed a modest advantage for switching outside the SSRI class ([Papakostas et al. 2008](#)).

Both venlafaxine and desvenlafaxine have demonstrated preventive efficacy in studies of longer-term therapy of MDD ([Boyer et al. 2015](#); [Rickels et al. 2010a](#); [Simon et al. 2004](#)). A large long-term study of patients with recurrent depression similarly demonstrated significant prophylactic effects for venlafaxine (versus placebo) after 12 months ([Kocsis et al. 2007](#)) and 24 months ([Keller et al. 2007](#)) of maintenance therapy. This study also included an active comparison group treated with fluoxetine. Although results were generally comparable across the acute and continuation phases and during the first year of maintenance treatment, a strong trend emerged during the second year of maintenance phase therapy suggesting greater efficacy for venlafaxine ([Thase et al. 2011](#)).

# Generalized Anxiety Disorder

Venlafaxine XR was approved by the FDA for the treatment of GAD on the basis of a series of placebo-controlled RCTs (see [Thase and Sloan 2006](#)). Across studies, efficacy was established for dosages ranging from 75 mg/day to 225 mg/day, with little evidence of a dose-response relationship. Sustained efficacy across 12 months was subsequently demonstrated in a study using a classic placebo-controlled discontinuation design ([Rickels et al. 2010b](#)).

With respect to comparative efficacy, the superiority of venlafaxine XR to buspirone was found on some—although not all—measures in one study ([Davidson et al. 1999](#)), and neither venlafaxine nor diazepam was found to be effective in the only study to use a benzodiazepine comparison group ([Hackett et al. 2003](#)). Venlafaxine XR, when compared with duloxetine and escitalopram, was found to be comparably effective in the only studies of GAD to use antidepressant comparators ([Allgulander et al. 2008](#); [Bose et al. 2008](#)).

## Social Anxiety Disorder (Social Phobia)

Venlafaxine XR was approved for the treatment of social anxiety disorder on the basis of a series of RCTs that confirmed its efficacy and safety relative to placebo across up to 6 months of double-blind therapy (see [Thase and Sloan 2006](#)). As was the case in GAD, effective dosages ranged from 75 mg/day to 225 mg/day, with little evidence of an ascending dose-response relationship. In the two studies that included paroxetine as an active comparator,

the SSRI and the SNRI were comparably effective and similarly well tolerated ([Allgulander et al. 2004](#); [Liebowitz et al. 2005](#)).

## Panic Disorder

The efficacy of venlafaxine XR in panic disorder was demonstrated in three placebo-controlled studies of acute-phase therapy ([Bradwejn et al. 2005](#); [Pollack et al. 2007a, 2007b](#)). These studies, which used a 37.5-mg/day starting dosage to minimize side effects, established an effective dosage range for venlafaxine of 75–225 mg/day. Two of the studies included paroxetine (40 mg/day) as an active comparator ([Pollack et al. 2007a, 2007b](#)). In the first comparison study, two fixed dosages of venlafaxine XR (75 mg/day or 150 mg/day) were comparable to paroxetine in both efficacy and tolerability ([Pollack et al. 2007a](#)). In the second comparison study, an RCT in which two fixed dosages (75 mg/day or 225 mg/day) were also used, the higher dosage of venlafaxine was significantly more effective than paroxetine on several secondary outcome measures, including proportion of patients experiencing complete relief from full-symptom panic attacks (70% vs. 58%) ([Pollack et al. 2007b](#)). Finally, a fourth study using a relapse prevention design demonstrated sustained efficacy for venlafaxine XR across 6 months of therapy ([Ferguson et al. 2007](#)).

## Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder

The efficacy of venlafaxine therapy in posttraumatic stress disorder was established in two large placebo-controlled studies ([Davidson et al. 2006a, 2006b](#)). Although no pivotal studies of venlafaxine therapy were conducted in obsessive-compulsive disorder, the results of a 12-week single-blind study indicated that venlafaxine might be at least as effective as clomipramine and significantly better tolerated ([Albert et al. 2002](#)).

## Premenstrual Dysphoric Disorder

A double-blind RCT evaluated the efficacy of venlafaxine IR in the treatment of premenstrual dysphoric disorder in 157 women across four menstrual cycles ([Freeman et al. 2001](#)). Dosages ranged from 50 mg/day to 200 mg/day, with adjustments for adverse events or lack of efficacy early in each cycle. Analyses of daily symptom rating scores revealed significantly greater improvement in the venlafaxine group compared with the placebo group at endpoint on the primary factors of emotion, function, physical symptoms, and pain.

## Vasomotor Symptoms Associated With Menopause

An extensive research program evaluated the efficacy, tolerability, and safety of desvenlafaxine for the treatment of vasomotor symptoms associated with menopause (see [Sun et al. 2013](#) and [Tella and Gallagher 2014](#) for a meta-analysis and a review, respectively). Evidence confirmed the efficacy of desvenlafaxine at dosages of at least 100 mg/day

and showed safety and tolerability profiles comparable to those seen in studies of MDD. Despite such findings, the FDA did not approve desvenlafaxine for this indication. Although less extensively studied than desvenlafaxine, venlafaxine also is widely used for the treatment of vasomotor symptoms associated with menopause, with an efficacy profile comparable to that of SSRIs ([Davari-Tanha et al. 2016](#); [Ensrud et al. 2015](#)). Likewise, venlafaxine has been shown to be an effective treatment for hot flashes and related symptoms following total hysterectomy in cancer patients ([Ramaswami et al. 2015](#)).

## Treatment of Children and Adolescents

Neither venlafaxine XR nor desvenlafaxine is approved for the treatment of individuals younger than 18 years. Six studies of venlafaxine XR and one study of desvenlafaxine have been completed in pediatric populations. With respect to venlafaxine, there were a pair of studies in MDD ([Emslie et al. 2007](#)), two RCTs in GAD ([Rynn et al. 2007](#)), one study in social anxiety disorder ([March et al. 2007](#)), and a large RCT in SSRI-resistant depression ([Brent et al. 2008](#)). For desvenlafaxine, there was one small study in MDD ([Findling et al. 2014](#)).

Results in the depression studies of venlafaxine XR (pooled  $N=334$ ) indicated that drug was significantly more effective than placebo among participants ages 12–17 years, but not among those ages 7–11 years ([Emslie et al. 2007](#)). Overall, venlafaxine XR therapy was associated with an increased risk of treatment-emergent suicidal and aggressive behaviors compared with placebo. In the pair of

GAD studies (pooled  $N=330$ ), venlafaxine XR was significantly more effective than placebo in the pooled data set; one study was unequivocally positive, but the second study failed to find a separation between drug and placebo on the primary outcome measure ([Rynn et al. 2007](#)). In the social anxiety disorder study ( $N=293$ ), venlafaxine XR was significantly more effective than placebo on both primary and secondary outcome measures ([March et al. 2007](#)). Finally, in a large National Institute of Mental Health-funded study of adolescents with a history of nonresponse to antidepressant medication, switching to venlafaxine XR therapy was no more effective—and was somewhat less well tolerated—than switching to a second SSRI. Both venlafaxine XR and SSRIs were more effective when used in combination with cognitive-behavioral therapy than when used as monotherapy ([Brent et al. 2008](#)).

[Findling et al. \(2014\)](#) conducted an 8-week open-label, fixed-dose multicenter study of desvenlafaxine in children ( $n=20$ ; ages 7–11 years) and adolescents ( $n=20$ ; ages 12–17 years) with MDD. Children received dosages of 10–100 mg/day, and adolescents received 25–200 mg/day. Desvenlafaxine was generally tolerable, with only 4 children (20%) and 3 adolescents (15%) withdrawing from treatment because of side effects. Both pulse rates and blood pressures increased significantly during treatment; however, there were no cases in which these values were judged to be of clinical concern. Although the absence of a placebo control group precluded an assessment of efficacy, mean Hamilton Rating Scale for Depression (Ham-D; [Hamilton 1960](#)) total scores decreased by more than 50% during the 8-week fixed-dose study, and these improvements were sustained across 6 months of flexible-

dose extension therapy. Two adolescents reported suicidal ideation before and during desvenlafaxine treatment.

---

## Side Effects and Toxicology

---

The tolerability profiles of venlafaxine and desvenlafaxine include all of the characteristic side effects associated with 5-HT uptake inhibition (i.e., nausea, insomnia, tremor, and sexual dysfunction) as well as side effects attributable to norepinephrine reuptake inhibition (i.e., sweating, light-headedness, and dry mouth); therefore, therapy with these SNRIs is associated with a somewhat higher side-effect burden than is usual with the SSRIs ([Schueler et al. 2011](#); [Thase and Sloan 2006](#)). In the meta-analysis of patient-level data conducted by [Nemeroff et al. \(2008\)](#), for example, 11% of the patients treated with venlafaxine withdrew from therapy because of adverse events, compared with 9% of the patients treated with SSRIs. Because relatively low dosages of desvenlafaxine are now recommended, its side-effect profile in controlled studies tends to be more favorable than that of venlafaxine ([Coleman et al. 2012](#)). Available evidence suggests that rates of sexual side effects with venlafaxine or desvenlafaxine are comparable to those with SSRIs ([Clayton et al. 2002](#); [Kennedy et al. 2000](#); [Montejo et al. 2001](#); [Serretti and Chiesa 2009](#)).

Venlafaxine and desvenlafaxine do not adversely affect cardiac conduction or lower the seizure threshold at therapeutic dosages. Both drugs are associated with small average increases in pulse rate and dose-dependent increases in the risk of elevated blood pressure ([Clayton et al. 2009](#); [Thase 1998](#); [Thase et al. 2015](#)). It is recommended

that blood pressure be documented before initiating therapy with these medications and that blood pressure be periodically checked during ongoing therapy. At higher therapeutic dosages, venlafaxine is associated with a reduction in heart rate variability ([Davidson et al. 2005](#)); this effect may be exaggerated when venlafaxine is prescribed in combination with certain other medications, including mirtazapine or quetiapine ([Huang et al. 2016](#)).

Like the SSRIs, venlafaxine is associated with a small but significant increase in bleeding disorders. For example, in studies of the risk of bleeding following childbirth, venlafaxine was associated with an excess risk of postpartum hemorrhage (ranging from 1% to 4%) ([Gahr et al. 2015](#); [Hanley et al. 2016](#); [Palmsten et al. 2013](#)). In one study, the risk of bleeding during the final month of pregnancy was greater for SNRIs than for SSRIs ([Hanley et al. 2016](#)). Such risks have not yet been shown with desvenlafaxine, but given its substantial similarity to venlafaxine, comparable risks are likely to be demonstrated.

Venlafaxine and desvenlafaxine are classified by the FDA as pregnancy Category C drugs, indicating that there are no adequate and well-controlled studies in pregnant women and that the drugs should be used during pregnancy only if they are clearly clinically indicated. As noted above, venlafaxine has been associated with an increased risk of hemorrhage during or following delivery. Studies completed to date do not document an increased risk of any specific birth defect ([Lassen et al. 2016](#)). Venlafaxine and desvenlafaxine are excreted in human breast milk and therefore should not be taken by women who are breast-feeding.

It is well known that abrupt withdrawal of venlafaxine can result in “discontinuation-emergent” symptoms such as dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances ([Haddad 2001](#)). Available evidence suggests that desvenlafaxine may have somewhat less problematic discontinuation-emergent symptoms ([Montgomery et al. 2009](#)). To minimize discontinuation symptoms, therapy should be tapered over several weeks when possible, and prescribers should counsel patients not to abruptly stop taking their antidepressant medication.

A number of fatal overdoses of venlafaxine have been reported; there is less clinical experience with overdoses of desvenlafaxine. In nonfatal overdoses of venlafaxine, electrocardiogram changes (e.g., QT interval prolongation, bundle branch block, QRS prolongation), sinus and ventricular tachycardia, bradycardia, hypotension, altered level of consciousness (ranging from somnolence to coma), serotonin syndrome, and seizures have been reported ([Howell et al. 2007](#); [Whyte et al. 2003](#)).

In a study using pharmacoepidemiological data collected in the United Kingdom, findings suggested that venlafaxine may be more lethal in overdose than the SSRIs, albeit less so than the TCAs ([Buckley and McManus 2002](#); [Hawton et al. 2010](#)). Because the statistical measure used in these studies, the Fatal Toxicity Index ([Henry 1989](#)), is based on the number of overdose deaths per million prescriptions, findings are subject to use biases, in that the patients who are treated with venlafaxine in the current prescribing environment tend to have more severe and resistant psychiatric illnesses compared with patients who are treated with SSRIs, and thus may have greater inherent suicide risk ([Mines et al. 2005](#); [Rubino et al. 2007](#)).

Nevertheless, venlafaxine's apparent excess lethality in overdose might be attributable to adverse effects on the seizure threshold ([Whyte et al. 2003](#)) and on cardiac conduction ([Howell et al. 2007](#)) at extremely high plasma levels.

## Drug-Drug Interactions

---

Venlafaxine undergoes extensive metabolism in the liver by the cytochrome P450 (CYP) enzyme system, particularly by the CYP2D6 isoenzyme, which is the pathway for conversion of venlafaxine into *O*-desmethylvenlafaxine. People who are poor metabolizers of CYP2D6 thus have unusually low plasma levels of the metabolite ODV ([Preskorn et al. 2009](#)) and may be less likely to benefit from treatment with the parent drug than patients who are normal or extensive metabolizers ([Lobello et al. 2010](#); [Shams et al. 2006](#)). Such patients therefore could potentially be better candidates for therapy with desvenlafaxine than for therapy with the parent drug.

In vitro and in vivo studies have shown that venlafaxine and ODV are weak inhibitors of CYP2D6 and cause little or no inhibition of other CYP isoenzymes, including 1A2, 2C9, 2C19, and 3A4 ([Ball et al. 1997](#); [Oganesian et al. 2009](#); [Owen and Nemeroff 1998](#)).

Use of venlafaxine or desvenlafaxine is contraindicated in patients taking monoamine oxidase inhibitors (MAOIs) because of the risk of serotonin syndrome. As with TCAs and SSRIs, venlafaxine or desvenlafaxine should not be initiated until 2 weeks after discontinuation of an MAOI,

and MAOI therapy should not be initiated until at least 7 days after discontinuation of venlafaxine or desvenlafaxine.

---

## Conclusion

---

Venlafaxine, the first member of the SNRI class in the United States and much of the world, is one of the more effective newer-generation antidepressants, with an overall safety profile that is intermediate between that of the SSRIs and that of the TCAs. There is evidence of an efficacy advantage for venlafaxine over fluoxetine and perhaps over other SSRIs; however, such an advantage has not been specifically demonstrated for all members of the SSRI class, most particularly escitalopram. Venlafaxine's treatment efficacy has also been established in GAD, social anxiety disorder, and panic disorder. Desvenlafaxine, which is approved only for the treatment of MDD, has several advantages relative to venlafaxine, including simpler dosing and metabolism that is not dependent on CYP2D6. Until generic formulations of desvenlafaxine are available, however, it seems likely that it will be more cost-effective to use generic formulations of venlafaxine XR, except for patients who cannot tolerate venlafaxine or who are known to be poor CYP2D6 metabolizers.

## CHAPTER 20

# Duloxetine, Milnacipran, and Levomilnacipran

### History and Discovery

Duloxetine was first synthesized in the late 1980s and subsequently patented in 1991. It was approved by the U.S. Food and Drug Administration (FDA) for the treatment of major depressive disorder (MDD) and diabetic neuropathy in the third quarter of 2004. This long delay after the initiation of clinical investigations was the result of the drug's initial testing in depressed patients at low dosages of 5–20 mg/day, which were not efficacious. Duloxetine has subsequently received approval almost worldwide.

Although milnacipran was approved for the treatment of MDD in France in 1996 and has long been used for that indication in various countries worldwide, it has not received FDA approval for the treatment of MDD. Its sole approved indication in the United States (received in 2009) is for the treatment of fibromyalgia. Levomilnacipran, the active enantiomer of milnacipran, was approved for MDD in the United States in 2013 and in Canada in 2015.

### Structure-Activity Relations

Duloxetine, milnacipran, and levomilnacipran ([Figure 20-1](#)), along with venlafaxine, are antidepressant medications that can act as both serotonin (5-hydroxytryptamine; 5-HT) and norepinephrine reuptake inhibitors. Whereas selective serotonin reuptake inhibitors (SSRIs) target only the serotonin transporter (5-HTT), the dual-acting medications have the potential to inhibit both the 5-HTT and the norepinephrine transporter (NET). Collectively, these three medications are referred to as *serotonin-norepinephrine reuptake inhibitors* (SNRIs). Several lines of evidence must be considered, however, to determine at which concentrations SNRIs are indeed effective dual reuptake inhibitors. This is of crucial importance in estimating their potency in clinical settings.

## Pharmacological Profile

### In Vitro Assessments

The first data to consider in determining the biochemical profile of reuptake inhibitors are their affinity values for membranal carriers. Finding these values involves determining the concentration of a medication necessary to displace 50% of the specific binding of a standard ligand for a given transporter subtype in a cell lysate preparation. This technique generally provides rough estimates of the potential for drugs to inhibit reuptake. A somewhat more informative approach involves determining the concentration of a drug necessary to inhibit the uptake of a given transmitter in intact cells from either animal brains or human cell lines. These physiological results are more reliable than mere binding data because of the integrity of the tissue. Indeed, data indicate that for some norepinephrine reuptake blockers, binding varies markedly depending on whether they are tested in membrane preparations or in intact cells, whereas for others, such as tricyclic antidepressants (TCAs), binding does not vary ([Mason et al. 2007](#)). As can be seen in [Table 20-1](#), both the absolute potencies and the ratios vary between the two preparations.

## In Vivo Assessments

Ideally, the potency of reuptake inhibitors in animal experiments should be assessed in vivo with the medications administered peripherally. One common technique involves the use of microdialysis studies in which extracellular levels of neurotransmitters are estimated from the perfusion of artificial cerebrospinal fluid. Data generated with duloxetine indicate that it first increases the levels of serotonin in the rat brain, and with escalating dosage it then increases the levels of norepinephrine ([Koch et al. 2003](#)). In the case of milnacipran, the levels of serotonin and norepinephrine are generally increased to the same extent (in guinea pigs; [Moret and Briley 1997](#)), although pronounced regional differences have been observed ([Bel and Artigas 1999](#)). Levomilnacipran increases rat cortical extracellular levels of norepinephrine and serotonin, with a norepinephrine-to-serotonin potency ratio of 2:1 ([Auclair et al. 2013](#)).

Potency ratios also can be assessed in vivo with electrophysiological approaches. Specifically, by determining the capacity of reuptake inhibitors to suppress the firing of norepinephrine and serotonin neurons, reliable potency estimates can be obtained. As reuptake transporters are dose-dependently inhibited from their peripheral injection, there will be an accumulation of serotonin and norepinephrine at the cell-body level of those neurons that will activate their respective autoreceptors, thereby decreasing their firing activity. Use of this technique reveals that duloxetine suppresses the firing rate of serotonin neurons by 50% with an intravenous dose of 0.1 mg/kg and that of norepinephrine neurons with 0.5 mg/kg ([Kasamo et al. 1996](#)). This in vivo ratio of 1:5 is therefore quite different from the in vitro affinity ratio of 1:12 ([Vaishnavi et al. 2004](#); see [Table 20-1](#)). In contrast, use of the same technique reveals that the dose of milnacipran necessary to inhibit the firing rate of serotonin neurons by 50% is 5.7 mg/kg ([Mongeau et al. 1998](#)). The latter results therefore suggest that milnacipran is a much less potent inhibitor of serotonin reuptake than is duloxetine.

## Assessments of Serotonin and Norepinephrine Reuptake in Humans

Reuptake of neurotransmitters cannot be assessed as directly in humans as it can be in the brains of laboratory animals. However, several approaches can provide useful estimates. For instance, serotonin reuptake inhibition can be estimated with blood platelet uptake of radioactive serotonin, because platelets do not synthesize serotonin and they contain a 5-HTT that is nearly identical to the one present on serotonin neurons in the brain. And because more than 90% of the serotonin present in the blood is in platelets, whole-blood serotonin depletion by a reuptake inhibitor is an even simpler measure. With use of a peripheral (platelet) assay, duloxetine produces a dose-dependent depletion of the serotonin level that reaches about 60% with a dosage of 60 mg/day, an effect still significantly inferior to that seen with 100 mg/day of the TCA clomipramine (Turcotte et al. 2001). Milnacipran produces only a 64% inhibition of serotonin uptake with the usual recommended dosage of 100 mg/day (Palmier et al. 1989). By comparison, platelet assays reveal that SSRIs produce greater than 80% inhibition of serotonin uptake at clinically effective dosages (Gilmor et al. 2002).

Occupancy of the 5-HTT in the human brain can be assessed directly through positron emission tomography (PET) studies using carbon 11 ( $^{11}\text{C}$ )-labeled ligands of this transporter. All SSRIs and venlafaxine produce 80% occupancy of the 5-HTT at their minimum effective dosages in depression (Meyer et al. 2004). A duloxetine daily dosage of 60 mg, but not of 40 mg, produces a sustained 80% occupancy (Takano et al. 2006). PET studies show that milnacipran daily dosages of 100 mg and 200 mg produce 5-HTT occupancies of 40% and 60%, respectively (Nogami et al. 2013). To our knowledge, levomilnacipran has not been tested with this approach.

Researchers have attempted to assess occupancy of the NET in the human brain with PET. However, issues remain regarding the specificity of the reboxetine derivative used in several reports (i.e., the lack of a plasma concentration-occupancy relation; Takano et al. 2014). A variety of peripheral measures can, however, be used. In particular, the intravenous tyramine pressor test has produced consistent results. Tyramine penetrates into peripheral norepinephrine terminals through the NET and releases norepinephrine in a calcium-independent manner, thereby transiently elevating the systolic blood pressure. Any drug that effectively blocks the NET attenuates this pressor response in a dose-dependent manner. Whereas the SSRIs paroxetine and sertraline do not affect pressor response, the TCAs desipramine, nortriptyline, and clomipramine attenuate the pressor response, as also do the selective norepinephrine reuptake inhibitors maprotiline, reboxetine, and atomoxetine (Blier et al. 2007; Gobbi et al. 2003; Harvey et al. 2000; Turcotte et al. 2001). Venlafaxine significantly attenuates the tyramine response in depressed patients only at dosages in the range of 225–375 mg/day (Blier et al. 2010; Debonnel et al. 2007). Duloxetine exerts a clear effect starting at 120 mg/day (Vincent et al. 2004), whereas milnacipran and levomilnacipran have not yet been tested in this model. A variety of other peripheral measures suggest that duloxetine may begin to inhibit norepinephrine reuptake at 60 mg/day (Chalon et al. 2003; Vincent et al. 2004).

Taken together, these results obtained in humans indicate that duloxetine is a potent serotonin reuptake inhibitor at 60 mg/day. The exact degree of norepinephrine reuptake inhibition occurring in humans at a duloxetine dosage of 60 mg/day remains unclear, but duloxetine clearly achieves physiologically relevant norepinephrine reuptake inhibition at a dosage of 120 mg/day. A definitive answer regarding the degree of norepinephrine reuptake inhibition produced by duloxetine in the human brain awaits the availability of a specific PET ligand for the NET. Such experiments also will help determine the NET reserve beyond which the overall function of the norepinephrine system is altered, as was determined for the 5-HTT (i.e., 80%; Meyer et al. 2004).

Milnacipran appears to preferentially block norepinephrine reuptake, as has easily been demonstrated in the brains of laboratory animals even at low doses ([Bel and Artigas 1999](#); [Mongeau et al. 1998](#)), whereas blockade of serotonin reuptake can only be documented with high doses. In humans, robust serotonin reuptake inhibition (>80% transporter blockade) appears to be achieved only with supratherapeutic doses (i.e., 300–400 mg; [Palmier et al. 1989](#)). Similar preclinical results have been obtained with levomilnacipran ([Auclair et al. 2013](#)).

---

## Mechanism of Action

---

SNRIs produce rapid inhibition of reuptake transporters in the brain, but their antidepressant effects are generally not seen for at least 2 weeks. Extensive electrophysiological and microdialysis studies in laboratory animals have consistently shown a similar delay before SNRIs produce a net enhancement of serotonin and/or norepinephrine transmission (see [Blier 2006](#) for a review). This delay may occur because, as a result of 5-HTT inhibition, potent serotonin reuptake inhibitors initially suppress the firing of serotonin neurons through activation of serotonin type 1A (5-HT<sub>1A</sub>) autoreceptors on neuron cell bodies. After 2–3 weeks of sustained administration, 5-HT<sub>1A</sub> autoreceptors desensitize, and the serotonin neuronal firing rate returns to normal. At this point, there is a net enhancement of 5-HT transmission in the forebrain ([Blier and De Montigny 1983](#)).

In the case of drugs that inhibit the NET, the firing rate of norepinephrine neurons is promptly diminished through activation of the  $\alpha_2$ -adrenergic autoreceptors on neuron cell bodies. After 2–3 weeks of sustained administration, the firing rate remains attenuated because the cell body  $\alpha_2$ -adrenergic autoreceptors do not become desensitized. In contrast,  $\alpha_2$ -adrenergic autoreceptors on norepinephrine terminals generally become desensitized with sustained administration, leading to a net enhancement of norepinephrine transmission in the forebrain ([Invernizzi and Garattini 2004](#); [Rueter et al. 1998a, 1998b](#); [Szabo and Blier 2001](#)).

## Pharmacokinetics and Disposition

---

### Absorption and Distribution

#### Duloxetine

Duloxetine is available in an enteric-coated formulation. It is rapidly absorbed after oral administration, and its absorption is not altered by food. Duloxetine's plasma level is proportional to dose, up to a maximum of 60 mg twice daily. It is highly (about 90%) bound to its plasma proteins. Its plasma elimination half-life is approximately 12 hours ([Sharma et al. 2000](#)). On repeated administration, duloxetine takes approximately 3 days to reach a steady-state level.

#### Milnacipran and Levomilnacipran

Milnacipran and levomilnacipran have low (13% and 22%, respectively) and nonsaturable plasma protein binding. They are rapidly absorbed after oral administration and have high bioavailability, and their absorption is not affected by food intake. They have no active

metabolites, and their elimination half-life is 8 hours. Steady-state levels are thus achieved within 3 days, with no drug accumulation occurring during prolonged dosing, and milnacipran and levomilnacipran are cleared from the body within 3 days of treatment cessation.

## Metabolism and Elimination

### Duloxetine

Duloxetine is extensively metabolized through various pathways ([Skinner et al. 2003](#)). Numerous metabolites are found in circulation, none of which is believed to contribute to duloxetine's therapeutic activity. Duloxetine is metabolized mainly by cytochrome P450 (CYP) 1A2 and 2D6 isoenzymes.

### Milnacipran and Levomilnacipran

The CYP system is not involved in the metabolism of milnacipran or levomilnacipran ([Briley 1998](#); [Chen et al. 2015](#)). Their metabolism is mainly mediated through phase II conjugation. They are eliminated by the kidneys; approximately 50%–60% of the drugs are recovered in the urine as the parent compounds and 20% as their glucuronide conjugates. The remainder of the metabolites are excreted mainly as an *N*-dealkyl metabolite and its glucuronide conjugate and in negligible amounts as an *N*-didealkyl metabolite and a hydroxy metabolite ([Brunner et al. 2015](#); [Chen et al. 2015](#); [Puozzo and Leonard 1996](#); [Puozzo et al. 2002](#)).

---

## Indications and Efficacy

---

Duloxetine is FDA approved for use in the treatment of MDD and diabetic peripheral neuropathic pain; in Europe, it is also approved for the treatment of stress urinary incontinence. The fact that SNRIs are effective in anxiety disorders is consistent with a noradrenergic mechanism ([Montoya et al. 2016](#)).

Although milnacipran is used to treat MDD in various countries, it has not yet received FDA approval for that indication. In the United States, milnacipran is approved only for the treatment of fibromyalgia, and levomilnacipran is approved only for treatment of MDD. Clinical practice has shown us the efficacy of these two molecules in both conditions, despite the lack of controlled studies, because and of fact that levomilnacipran is the active enantiomer of milnacipran.

## Major Depressive Disorder

### Duloxetine

To date, 17 placebo-controlled studies have examined the antidepressant efficacy of duloxetine at dosages of 40–120 mg/day. (These studies and non-placebo-controlled duloxetine trials are summarized in [Tables 20–2](#) and [20–3](#).) Several of these studies had an active drug comparator group. Head-to-head comparisons with SSRIs and SNRIs have yielded mixed results, which appear to be influenced by dosing regimens ([Cipriani et al. 2012](#)). Overall, no statistically significant difference in efficacy was found between duloxetine and other drugs to treat MDD.

In a meta-analysis comparing SNRIs and SSRIs in the treatment of MDD, duloxetine 40–120 mg/day was found to be an effective antidepressant with an overall efficacy profile equal to that of fluoxetine and paroxetine at 20 mg/day ([Thase et al. 2007](#)). For patients with more severe symptoms, remission rates with duloxetine were statistically superior to those with the SSRIs. A meta-analysis of nine randomized controlled trials (RCTs) evaluating higher dosages of duloxetine in patients with severe depression concluded that duloxetine 120 mg/day produced significantly greater baseline-to-endpoint improvement versus placebo on several of the 17-item Hamilton Rating Scale for Depression (Ham-D-17) items ([Shelton et al. 2007a, 2007b](#)). These results indicate that for duloxetine, the higher dosage that achieves consistent norepinephrine reuptake inhibition may be more effective than the lower dosage that achieves only serotonin reuptake inhibition ([Chalon et al. 2003](#); [Turcotte et al. 2001](#); [Vincent et al. 2004](#)). This assertion was also made in a large open-label study in which patients who did not respond to 60 mg/day after 4 weeks improved with an up-titration to 120 mg/day ([Sagman et al. 2011](#)).

## Milnacipran

A meta-analysis of three short-term (4- to 8-week) double-blind, acute efficacy multicenter trials in inpatients and outpatients with moderate to severe depression concluded that milnacipran provides a superior antidepressant effect compared with placebo at dosages of 50 mg and 100 mg twice daily but not at a dosage of 25 mg twice daily ([Lecrubier et al. 1996](#); [Macher et al. 1989](#)).

Several studies have compared milnacipran with SSRIs or TCAs ([Table 20-4](#)). Milnacipran was noted to have equal efficacy but superior tolerability relative to the TCA imipramine ([Puech et al. 1997](#)). A meta-analysis concluded that evidence was insufficient to suggest a difference in response rates between milnacipran and any SSRI. Pooling response rates between agents yielded an overall response rate of 62% for milnacipran

and of 58% for the SSRIs (Papakostas and Fava 2007). A 24-week randomized, double-blind study demonstrated the safety, tolerability, and efficacy of flexible dosages of milnacipran and venlafaxine (100–200 mg/day) in MDD (Olié et al. 2010). There is no maximum recommended dosage for milnacipran, but it is important to note that the highest daily dosage tested so far, 300 mg, was tested in only 41 patients and for only 2 weeks (Ansseau et al. 1991). The maximum recommended dosage of milnacipran in fibromyalgia is 200 mg/day.

<sup>a</sup>Milnacipran was given once daily; this was in contrast to the other studies, in which it was administered on a twice-daily basis.

<sup>b</sup>This was a composite of two positive controlled studies.

### Levomilnacipran

Although it is recommended that levomilnacipran be started at 20 mg/day for the first few days, the minimum effective dosage of 40 mg/day is generally well tolerated as a starting dosage. The dosage can then be increased to 80 mg/day and 120 mg/day, according to tolerability and response. Four of the five controlled studies (involving a total of 3,020 patients) reported effectiveness for the 40–120 mg/day dosage range in patients with MDD ages 18–80 years (Table 20-5). No active comparator study has yet been published.

## Neuropathic and Chronic Pain

### Duloxetine

TCAs and SNRIs clearly produce significant relief of physical symptoms, such as pain in depression and in a variety of pain syndromes ([Stahl et al. 2005](#)). Duloxetine exerts a prompt and substantial analgesic effect over and above its antidepressant action ([Perahia et al. 2006a](#)). Potentiation of the activity of serotonin and norepinephrine is believed to result in central pain inhibition through descending modulatory pathways ([Sussman 2003](#)).

In an 8-week study, duloxetine at a fixed dosage of 60 mg/day significantly reduced pain measures from baseline to endpoint compared with placebo in patients with MDD and at least moderate pain. At 8 weeks, the mean average pain score on the Brief Pain Inventory—Short Form was close to 3, which can be considered a mild level of pain compared with the moderate or higher levels of pain indicated by baseline scores (5.8; [Brecht et al. 2007](#)). Similarly, elderly patients with depression who received duloxetine 60 mg/day for 8 weeks showed significant improvement on back pain scores and amount of time in pain compared with patients who received placebo ([Raskin et al. 2007](#)). In an RCT evaluating the efficacy of duloxetine 60 mg/day in patients with MDD and associated painful physical symptoms, the drug was superior to placebo in reducing overall, shoulder, and back pain, as well as time spent in pain ([Detke et al. 2002a](#)).

### Milnacipran

The capacity of milnacipran to relieve chronic pain has been reported in open trials, but no RCTs have been published to date.

## Fibromyalgia

### Duloxetine

A 12-week RCT of duloxetine 120 mg/day versus placebo in patients with fibromyalgia with or without depression found significant improvement in pain scores and in tender points in duloxetine recipients compared with placebo recipients ([Arnold et al. 2005](#)). Duloxetine 120 mg/day improved fibromyalgia symptoms and pain severity regardless of the extent of the accompanying depressive disorder. This direct effect of duloxetine on painful physical symptoms was later confirmed ([Robinson et al. 2013](#)).

### Milnacipran

An initial placebo-controlled study of milnacipran in fibromyalgia patients found that 37% of those who received 100 mg of milnacipran twice daily experienced a significant reduction (50% or more) in pain intensity compared with 14% of those who received placebo ([Vitton et al. 2004](#)). Subsequent studies led to milnacipran's approval in the United States for fibromyalgia ([Häuser et al. 2011](#)).

## Stress Urinary Incontinence

Duloxetine has been shown to be efficacious in the treatment of stress urinary incontinence, with 40 mg twice daily being the recommended dosage ([Li et al. 2013](#)). Serotonin and norepinephrine increase excitatory glutamate transmission in the Onuf nucleus in the sacral spinal cord, which facilitates urethral sphincter contraction ([Thor 2003](#)). This presumably is the mechanism for duloxetine's beneficial effects in the treatment of this problem.

---

## Side Effects and Toxicology

---

### Duloxetine

The safety and tolerability of duloxetine at a dosage range of 40–120 mg/day have been assessed in a number of clinical trials. In an 8-month study, the most common treatment-emergent adverse events were nausea, dry mouth, vomiting, yawning, and night sweats ([Pigott et al. 2007](#)). Most of these effects emerged early, within the first 8 weeks of treatment. Other studies have reported insomnia, somnolence, headaches, ejaculation disorders, diarrhea, constipation, and dizziness as common adverse events with duloxetine ([Detke et al. 2002a, 2002b](#); [Khan et al. 2007](#); [Nierenberg et al. 2007](#)).

The incidence of nausea associated with duloxetine appears to be comparable to that associated with other SSRIs and SNRIs. Nausea is transient and is usually experienced on treatment initiation. A starting dosage of 60 mg/day appears to provide the best combination of clinical response and tolerability ([Bech et al. 2006](#); [Pritchett et al. 2007](#)). Clinicians may, however, consider starting at a lower dosage (30 mg/day) for patients in whom tolerance is a concern. Compared with a duloxetine dosage of 60 mg/day, a dosage of 30 mg/day was associated with a lower rate of nausea (16%, vs. 33% for 60 mg/day) and was preferred by the majority of female patients ([Dunner et al. 2005](#); [Wilhelm et al. 2012](#)). The initial tolerability of duloxetine at 60 mg/day can be improved if the drug is taken with food; it then has tolerability comparable to an initial dosage of 30 mg/day ([Whitmyer et al. 2007](#)).

Duloxetine has not been associated with weight gain, and in one study it was in fact noted to be associated with a mean weight loss of 1 kg ([Nierenberg et al. 2007](#)). This

decrease was a significant difference compared with the lack of effect that placebo and escitalopram had on weight.

Changes in blood pressure and heart rate associated with duloxetine treatment do not appear to be clinically significant. Pooled data from 735 patients receiving duloxetine 40–120 mg/day showed that 0.7% experienced a 10 mm Hg increase in systolic or diastolic blood pressure, versus 0.4% of patients receiving placebo. Heart rate was increased by less than 1 beat per minute ([Schatzberg 2003](#)).

Rates of sexual dysfunction, including anorgasmia, erectile dysfunction, delayed ejaculation, and decreased libido, appear to be low with duloxetine. Researchers found that after 8 months, categorical outcomes shown on a questionnaire about changes in sexual functioning did not differ significantly between duloxetine- and escitalopram-treated groups ([Pigott et al. 2007](#)). In clinical practice, however, any drug that strongly inhibits serotonin reuptake has the potential to cause problematic sexual dysfunction in a significant proportion of patients.

A significantly higher rate of treatment discontinuation was reported among patients who were randomly assigned to receive duloxetine compared with those who were assigned to receive escitalopram or venlafaxine ([Cipriani et al. 2012](#)). It appears that study participants who discontinue duloxetine because of adverse events often do so during early treatment ([Nierenberg et al. 2007](#); [Perahia et al. 2008](#); [Pigott et al. 2007](#)), which may indicate poorer initial tolerability.

A systematic search of accumulated data for in utero exposure to duloxetine identified 16 major congenital malformations occurring in 668 infants, yielding a relative risk ratio of 0.8 ([Lassen et al. 2016](#)). Infant exposure to duloxetine through breast milk is less than 1% of the maternal weight-adjusted dosage ([Andrade 2014](#)). These figures suggest that duloxetine can be safely used during pregnancy and lactation.

## Milnacipran and Levomilnacipran

Analysis of a database of more than 3,300 patients concluded that the adverse-event profile of milnacipran in MDD was comparable to that of the SSRIs, except that the SSRIs were associated with a higher frequency of nausea and anxiety, whereas milnacipran was associated with a higher incidence of dysuria ([Puech et al. 1997](#)). Weight gain is uncommon, but sedation may be reported. Although data on rates of sexual dysfunction with milnacipran have not been reported, the incidence is estimated to be low compared with that associated with venlafaxine and SSRIs ([Stahl et al. 2005](#)). The lower incidence of nausea and sexual dysfunction with milnacipran relative to the SSRIs may be taken as indirect evidence of milnacipran's lower serotonin reuptake inhibition potential, given that these two treatment-emergent adverse events are classically induced by potent serotonin reuptake inhibitors.

Blood pressure increases with milnacipran are minimal. A 12-week randomized, double-blind study comparing milnacipran dosages of 100 mg/day and 200 mg/day versus fluoxetine 20 mg/day in 289 depressed inpatients found no significant changes in blood pressure in any of the groups ([Guelfi et al. 1998](#)). Tachycardia (defined as a heart rate greater than 100 beats per minute) was seen in 0% of patients receiving fluoxetine, 3% of patients receiving milnacipran 100 mg/day, and 6% of patients receiving milnacipran 200 mg/day. A review of more than 4,000 patients taking milnacipran for MDD showed that the mean increase in blood pressure was less than 1 mm Hg, and the mean increase in heart rate was 4 beats per minute ([Puech et al. 1997](#)). Given that an increase in heart rate is a thumbprint of potent norepinephrine reuptake inhibition, this increase is consistent with

the capacity of milnacipran to effectively block norepinephrine reuptake. No cardiotoxicity has been reported with overdoses of up to 2.8 g/day, which is 28 times the recommended daily dose ([Montgomery et al. 1996](#)).

An analysis of the long-term safety of milnacipran (in 715 patients with MDD receiving milnacipran for >6 months, and 189 for >12 months, as reported by [Puech et al. 1997](#)) concluded that most adverse events appeared within the first 3 months of treatment and that the incidence decreased steadily thereafter. More important, no treatment-emergent adverse events developed during long-term treatment.

The adverse-event profile of levomilnacipran is similar to that of milnacipran and basically relates to noradrenergic mechanisms. Common side effects include hyperhidrosis, increased heart rate, elevation of blood pressure, urinary hesitancy, constipation, and nausea. These effects are generally of low intensity and seldom lead to discontinuation. The QTc interval remains unaltered at all therapeutic dosages (40–120 mg/day) and is not prolonged to a clinically significant extent at a dosage of 300 mg ([Asnis and Henderson 2015](#)).

---

## Drug-Drug Interactions

---

Serotonin syndrome, a serious and potentially lethal pharmacodynamic interaction, can result if milnacipran, levomilnacipran, or duloxetine is taken concomitantly with a monoamine oxidase inhibitor (MAOI). To avoid this catastrophic outcome, an MAOI must not be initiated until at least 5 days after duloxetine, milnacipran, or levomilnacipran has been discontinued. A longer elimination period than that expected from plasma half-life is recommended, because brain elimination generally lags behind plasma elimination. At least a 14-day washout of MAOIs must be respected before starting any SNRI.

## Duloxetine

Inhibitors of CYP1A2, such as ciprofloxacin, increase plasma levels of duloxetine, and concomitant use may require that duloxetine dosages be reduced or that duloxetine be discontinued. When duloxetine is coadministered with a CYP2D6 inhibitor of moderate potency, such as bupropion or diphenhydramine, duloxetine levels may increase. However, such alterations of duloxetine levels are in general not clinically significant.

Duloxetine does not inhibit or induce the activity of the CYP1A2, 2C9, or 3A4 systems. It does, however, moderately inhibit the activity of the CYP2D6 isoenzyme. If duloxetine is coadministered with an agent metabolized by CYP2D6, clinicians should prescribe dosages that are approximately half those usually recommended for the concomitant medication. Duloxetine does not potentiate the psychotropic effects of ethanol or benzodiazepines.

## Milnacipran and Levomilnacipran

Because milnacipran and levomilnacipran are not metabolized by CYP pathways, they do not produce pharmacokinetic drug-drug interactions.

---

## Conclusion

---

At their minimum effective dosages, duloxetine (60 mg/day) and milnacipran (100 mg/day) potentially block the reuptake of serotonin and norepinephrine, respectively. In the case of duloxetine, it is difficult to imagine how an increase from a subtherapeutic dosage of 40 mg/day, at which it does not perform as a weak SSRI, to 60 mg/day could produce marked norepinephrine reuptake inhibition when the in vivo serotonin-to-norepinephrine reuptake potency ratio is 1:5. In the case of milnacipran, a 100-mg daily dosage produces suboptimal platelet serotonin reuptake inhibition. Duloxetine, at its maximum recommended dosage (120 mg/day), and milnacipran, at its upper therapeutic range (200 mg/day), are dual reuptake inhibitors. Consequently, none of the four SNRIs currently available can be considered equal reuptake inhibitors. They all show efficacy in the treatment of depression and pain syndromes, with emerging evidence also suggesting a potential role for duloxetine in the treatment of stress urinary incontinence and generalized anxiety disorder.

These medications are generally well tolerated, with most adverse effects occurring early in treatment, being mild to moderate in severity, and having a tendency to decrease or disappear with continued treatment.

Either duloxetine or milnacipran may be used as a first-line treatment for depression, because these medications are not toxic in overdose, and they can be used at a therapeutic dosage from treatment initiation onward with minimal side effects. Furthermore, data suggest that treatment with a dual reuptake inhibitor may be superior to treatment with an antidepressant with only one mechanism of action, such as an SSRI (Nemeroff et al. 2008; Poirier and Boyer 1999; Sagman et al. 2011; Thase et al. 2007). Consequently, these drugs may be beneficial in patients whose symptoms have been unresponsive to treatment with SSRIs and norepinephrine reuptake inhibitors, provided that they are taken at dosages at the upper end of the therapeutic range.

# CHAPTER 21

## Ketamine

David S. Mathai, B.S.

---

### History and Discovery

---

Ketamine emerged from the exploration of phencyclidine (PCP) derivatives suitable for anesthetic use in humans, and its discovery in 1962 is attributed to Parke-Davis Labs and Dr. Calvin Lee Stevens, a professor of organic chemistry at Wayne State University ([Domino et al. 1965](#)). Following approval by the U.S. Food and Drug Administration (FDA) in 1970, the drug was used as a battlefield anesthetic for American soldiers during the Vietnam War ([Jansen 2000](#)). Over the next several decades, as ketamine gained recognition for its dissociative properties, reports of its nonmedical use began to emerge, ultimately resulting in federal government classification of the drug as a Schedule III controlled substance in August 1999 ([Ahmed and Petchkovsky 1980](#); [Graeme 2000](#); [Shomer 1992](#)). Today

ketamine abuse is prevalent internationally, especially in parts of Asia, where it has been considered a long-standing problem, albeit one that appears to be stabilizing ([United Nations Office on Drugs and Crime 2014](#)). Countries such as the United Kingdom have seen a decrease in ketamine use but an increase in people seeking treatment for ketamine use. Medically, ketamine continues to be widely used as a general anesthetic in specific populations and also as an analgesic for pain unresponsive to standard treatments ([Persson 2013](#)). Psychiatric applications of ketamine are currently an area of intense investigation and encompass its use in treatment-resistant depression, as an antisuicidal agent, as an adjunct to electroconvulsive therapy (ECT), in obsessive-compulsive disorder (OCD), in posttraumatic stress disorder (PTSD), and as a pharmacological model of psychosis.

---

## Structure-Activity Relations

---

Ketamine (2-[2-chlorophenyl]-2-[methylamino]cyclohexanone) is an arylcycloalkylamine compound that is structurally similar to PCP and cyclohexylamine ([Figure 21-1](#)). The free-base form of ketamine is highly lipid soluble and is commercially available as an aqueous preparation of the hydrochloride salt. Ketamine is a chiral compound that exists pharmaceutically as a racemic mixture of (*S*)-ketamine (esketamine) and (*R*)-ketamine (arketamine) enantiomers.

---

**FIGURE 21-1.** Chemical structure of ketamine.

---

## Pharmacological Profile

---

Ketamine has high lipid solubility and low plasma protein binding. It undergoes biotransformation in the liver to norketamine, its primary active metabolite. Approximately 90% of ketamine is excreted in the urine in metabolite form with minimal clearance of unchanged drug, and another 5% undergoes fecal excretion ([Clements et al. 1982](#)). Ketamine has a wide therapeutic index and has been shown to have a low risk of lethal overdose ([Green et al. 1999](#)). Its main pharmacological action is on glutamate as an open-channel, nonselective *N*-methyl-D-aspartate (NMDA) receptor antagonist.

---

## Pharmacokinetics and Disposition

---

Ketamine can be administered by oral, intravenous, intramuscular, subcutaneous, intranasal, epidural, transdermal, intra-articular, and sublingual routes

([Kotlińska-Lemieszek and Luczak 2004](#)). When given orally, ketamine undergoes extensive hepatic biotransformation (via *N*-demethylation by cytochrome P450 [CYP] isoenzymes 3A4, 2C9, and 2B6) into norketamine, the drug's major metabolite. With oral administration of ketamine, norketamine has lower potency than the parent drug but higher plasma levels than those produced when ketamine is given intramuscularly ([Grant et al. 1981](#)). Hydroxynorketamine (HNK), a secondary metabolite also found at high levels soon after administration of ketamine, may play a role in the extended clinical responses that persist after ketamine has been metabolized ([Paul et al. 2014](#); [Singh et al. 2014](#)). Ketamine undergoes renal elimination, and dehydronorketamine (DHNK) is the inactive metabolite that is predominant in urine ([Sinner and Graf 2008](#)). The oral bioavailability of ketamine is 17%–20%; bioavailability for other routes is as follows: 25%–50% for intranasal, 30% for sublingual, 30% for rectal, 93% for intramuscular, and ~99%–100% for intravenous ([Clements et al. 1982](#); [Quibell et al. 2015](#)). Peak plasma concentrations are reached within 30–60 minutes of oral administration, 5–15 minutes of intramuscular injection, and 1 minute of intravenous injection ([Paul et al. 2014](#)). Ketamine is rapidly distributed to highly perfused tissues, including the brain, with a distribution half-life of approximately 10–15 minutes and an elimination half-life of 2–2.5 hours ([Domino et al. 1984](#)). The half-lives of ketamine metabolites are longer than that of the parent drug, measuring 5.3 hours and 6.9 hours for norketamine and DHNK, respectively ([Hijazi et al. 2003](#)).

---

# Mechanism of Action

---

Ketamine is a dissociative anesthetic with analgesic and amnesic properties ([Curran and Morgan 2000](#)). The anesthetic state produced by ketamine was initially termed “dissociative anesthesia” because an electrophysiological unlinking of the thalamoneocortical and limbic systems was thought to be the mechanism by which the drug exerted its primary effect on the central nervous system (CNS); however, the term was later generalized to capture a more psychological sensation of dissociation from self or the surrounding environment, often manifesting as a cataleptic-type state ([Haas and Harper 1992](#); [Jansen 1990](#); [Reich and Silvay 1989](#)). Ketamine has a very complex pharmacological profile, with variable, concentration-dependent affinities for numerous receptors ([Alkire et al. 2008](#); [Oye et al. 1992](#); [Rabiner 2007](#); [Sleigh et al. 2014](#); [Smith et al. 1981, 1987](#)). Off-target interactions at these receptors are responsible for ketamine’s transient cardiovascular, respiratory, and sympathomimetic effects ([Domino 2010](#)). Ketamine exerts its primary effect as a voltage-dependent nonselective NMDA receptor antagonist that inhibits transmembranous flux of calcium and sodium in the presence of the coagonists glutamate and glycine ([Niciu et al. 2014](#)). Of ketamine’s two enantiomers, (*S*)-ketamine has been shown to have a higher affinity for the NMDA receptor and a three- to fourfold greater anesthetic potency relative to (*R*)-ketamine, as well as increased psychotomimetic side effects ([Bergman 1999](#); [Kohrs and Durieux 1998](#)).

At the level of NMDA receptor blockade, ketamine is thought to interfere with multiple processes, including sensory input to higher CNS centers, emotional responses

to those stimuli, and learning and memory consolidation ([Bergman 1999](#)). Previous studies demonstrated that the NMDA receptor channel complex is integral to the central sensitization of dorsal horn neurons that transmit pain signals ([Petrenko et al. 2003](#)). When the channel is unblocked, neuronal hyperexcitability contributes to hyperalgesia, allodynia, and reduced opioid responsiveness; these effects are thought to be mediated by intracellular formation of nitric oxide and cyclic guanosine monophosphate (cGMP), along with interactions between opioid receptors and the NMDA receptor channel ([Mion and Villeveille 2013](#)). Ketamine-induced central antinociception has been shown to be antagonized in a dose-dependent manner by naloxone, clocinnamox, and naltrindole; to be potentiated by bestatin; and to be unaffected by norbinaltorphimine, suggesting the involvement of endogenous mu and delta (but not kappa) opioid receptors in ketamine's antinociceptive effects ([Pacheco et al. 2014](#)). In rodent models, ketamine's antinociceptive effects have also been attributed to stimulation of the L-arginine/nitric oxide/cGMP pathway via neuronal nitric oxide synthase ([Romero et al. 2011](#)).

Other studies have implicated neurotrophic signaling cascades in the antidepressant effects of ketamine ([Autry et al. 2011](#); [Browne and Lucki 2013](#); [Duman et al. 2012](#); [Haile et al. 2014](#); [Hashimoto et al. 2013](#); [Kavalali and Monteggia 2012](#); [Li et al. 2010, 2011](#)). Signaling changes include induction of mammalian target of rapamycin (mTOR) signaling and resultant synaptic remodeling, consistent with existing neuroplasticity-related theories of depression ([Duman 2014](#); [Duman and Li 2012](#); [Duman and Monteggia 2006](#); [Grady and Stahl 2013](#); [Murrough and Charney 2010](#)). Activation of mTOR is also thought to be mediated by

activation of the non-NMDA glutamate  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor and upregulation of brain-derived neurotrophic factor (BDNF) and tropomyosin-related kinase B (TrkB) signaling ([Duman and Voleti 2012](#)). Both norketamine and HNK have been shown to have significant pharmacological activity and may contribute to the therapeutic effects of subanesthetic doses of ketamine by antagonistic action at the alpha-7 nicotinic acetylcholine receptor ( $\alpha 7$ -nAChR) ([Quibell et al. 2015](#)).

---

## Indications and Efficacy

---

### Anesthesia

Ketamine gained FDA approval in 1970 for the following indications: 1) as the sole anesthetic agent for diagnostic and surgical procedures that do not require skeletal muscle relaxation, 2) for induction of anesthesia prior to administration of other general anesthetic agents, and 3) to supplement low-potency anesthetic agents, such as nitrous oxide ([Par Pharmaceutical Companies 2014](#)). Ketamine was an attractive drug for these indications because of its potent anesthetic properties and its safety profile, characterized by a large therapeutic window and low risk of respiratory depression. Recommended dosages for induction of anesthesia are 6.5–13.0 mg/kg intramuscular and 1.0–4.5 mg/kg intravenous, with alternative off-label recommendations for situations that involve administration of adjuvant drugs ([Miller et al. 2010](#)). For maintenance of anesthesia, the manufacturer recommends administering one-half to the full induction dose *or* a continuous infusion

of 0.1–0.5 mg/minute of ketamine; however, clinical studies have suggested that higher dosages may be needed to maintain an adequate concentration for anesthesia ([White et al. 1982](#)). Although only the racemic mixture of ketamine is marketed in the United States, (*S*)-ketamine was approved in Europe in 1998 and is available in a number of European Union countries for induction and maintenance of general anesthesia, supplementation of local anesthesia, and analgesia in emergency medicine.

## Off-Label Applications

### **Sedation, Analgesia, and Reduction of Postsurgical Pain, Nausea, and Vomiting**

In regard to off-label applications, various laboratory and clinical studies support the use of ketamine for sedation, analgesia, and improved postoperative outcomes ([Adam et al. 2005](#); [Green et al. 2011](#); [Hocking and Cousins 2003](#); [Menigaux et al. 2000](#); [Remérand et al. 2009](#); [Zakine et al. 2008](#)). A systematic review of low-dosage ketamine for chronic noncancer pain (e.g., neuropathic, ischemic, fibromyalgia) administered by multiple routes concluded that although ketamine provided relief, its long-term use should be restricted to controlled trials ([Bell 2009](#)). Another review of ketamine as an analgesic for phantom limb pain reached a similar conclusion ([Alviar et al. 2011](#)). Randomized controlled trial (RCT) evidence ([Schwartzman et al. 2009](#); [Sigtermans et al. 2009](#)) pointed to ketamine's benefit in complex regional pain syndrome type 1 at a variety of dosages and routes of administration; however, a larger review ([Azari et al. 2012](#)) suggested that stronger evidence (drawn from larger studies that include data on

unsuccessful trials) is needed before ketamine can be recommended for that indication. Subanesthetic doses of ketamine have also been found to be effective in the management of acute postoperative pain, reducing morphine requirements during the first 24 hours after surgery and additionally improving nausea and vomiting ([Bell et al. 2006](#)).

## **Relief of Acute Depression and Suicidal Ideation**

Multiple meta-analyses have confirmed ketamine's acute antidepressant effects in patients with major depressive episodes associated with major depressive disorder or bipolar disorder, including a reduction in suicidal ideation ([Caddy et al. 2014](#); [Fond et al. 2014](#); [Lee et al. 2015](#); [McGirr et al. 2015](#); [Price and Mathew 2015](#)). Data have shown rapid improvement of depressive symptoms in up to 71% of patients following administration of a single intravenous dose of ketamine (typically 0.5 mg/kg over 40 minutes), with response seen within hours and the peak antidepressant effect occurring at 24 hours ([aan het Rot et al. 2012](#); [Lee et al. 2015](#); [Mathew et al. 2012](#); [Salvadore and Singh 2013](#)). For patients who showed early benefit (within several days) from a single infusion, the mean duration of response was highly variable. In a Cochrane Review meta-analysis of 25 double-blind and single-blind RCT studies (1,242 participants) comparing intravenous administration of 11 different glutamate receptor modulators with placebo, other active psychotropic drugs, or ECT in adults with unipolar major depressive disorder, only ketamine showed a significant effect in reducing the acute symptoms of depression ([Caddy et al. 2015](#)).

Ketamine's antidepressant effects were evident at 1 week after treatment but had disappeared by 2 weeks. Ketamine was found to cause more confusion and emotional blunting than placebo. A systematic review evaluating the use of ketamine and other NMDA antagonists in depression also noted compelling evidence for the rapid, yet transient, antidepressant effects of ketamine infusion but recommended further investigation into ketamine's mechanism of action ([Newport et al. 2015](#)). The reviewers concluded that apart from ketamine, no NMDA antagonists consistently demonstrated antidepressant efficacy, although two partial agonists at the NMDA coagonist site, D-cycloserine and rapastinel, were found to significantly reduce depressive symptoms without causing psychotomimetic or dissociative effects.

In addition to studies on the antidepressant effects of ketamine, there is a need for further exploration of ketamine's effects on cognition, quality of life, and suicidality. Although ketamine has been demonstrated to provide rapid reduction in suicidal ideation in some patients with major depressive disorder, limited controlled data are available on ketamine's effects in patients with a more severe risk of suicide, such as patients who have been hospitalized for suicidal ideation or a suicide attempt ([Price and Mathew 2015](#)). Additional investigation is also needed regarding other modes (besides intravenous) of ketamine administration and the efficacy and safety of repeated administrations of the drug. Four studies of a series of four to six ketamine infusions administered over a 2-week interval reported relapse rates of 55%–89% in the month following treatment, although these studies were limited by small sizes and an open-label design ([van het Rot et al.](#)

2010; Murrough et al. 2013; Rasmussen et al. 2013; Shiroma et al. 2014).

## **Augmentation Agent in Electroconvulsive Therapy**

Ketamine's use in conjunction with ECT has also been explored. A 2015 systematic review and meta-analysis identified five studies ( $N=180$  adults with unipolar or bipolar depression) in which intravenous ketamine (0.5–2.0 mg/kg) was used either in addition to ([Abdallah et al. 2012](#); [Järventausta et al. 2014](#); [Loo et al. 2012](#)) or instead of ([X. Wang et al. 2012](#); [Yoosefi et al. 2014](#)) another agent—propofol, thiopental, or placebo—to induce anesthesia prior to ECT administration ([Newport et al. 2015](#)). Meta-analysis indicated that ketamine was associated with a significantly greater reduction in depressive symptoms after the initial ECT session; however, this advantage had disappeared by the end of the ECT course. Across the studies included within the review, the inclusion of ketamine in the ECT anesthetic regimen was associated with longer seizure durations (prolonged by an average of 11.49 seconds). A retrospective study comparing the effects of pre-ECT administration of ketamine, etomidate, thiopental, or propofol on seizure parameters and quality found that ketamine anesthesia was associated with higher-quality seizures (as defined by seizure duration and degree of central inhibition) than were produced with the other anesthetic agents ([Hoyer et al. 2014](#)). Although ketamine has been used reluctantly at times in ECT because of its potential to provoke dissociative symptoms, these study findings suggest that the drug's psychiatric side effects may be dose-dependent and may be effectively controlled

without relevant distress for patients. Furthermore, ketamine was found to be preferable to other anesthetic agents, with decreased induction of transient cognitive effects ([Hoyer et al. 2014](#)).

## Investigative Applications

Ketamine has been investigated in a number of other psychiatric conditions. Glutamate-modulating agents have been considered as therapeutic candidates in treatment-refractory OCD based on lines of evidence pointing to an underlying role of glutamate dysregulation in this disorder; however, studies examining the benefit of these agents in OCD have been inconclusive ([Pittenger 2015](#)). In a randomized, placebo-controlled crossover trial of ketamine in unmedicated patients with refractory OCD, participants who received ketamine first showed significant and rapid antiobsessional effects during the 0.5 mg/kg infusion that persisted until 1 week postinfusion, compared with participants who received placebo (saline infusion) first ([Rodriguez et al. 2013](#)). A subsequent study of the neurochemical effects of ketamine versus saline infusions using proton magnetic resonance spectroscopy ( $^1\text{H}$  MRS) suggested that the therapeutic effect of ketamine in OCD may in fact occur independently of the glutamate-glutamine activity ([Rodriguez et al. 2015](#)).

In patients with chronic PTSD, preliminary RCT evidence demonstrated that a single intravenous ketamine infusion (0.5 mg/kg) was associated with a significant and rapid reduction in PTSD symptom severity compared with midazolam when assessed 24 hours after administration

([Feder et al. 2014](#)). Ketamine was well tolerated, with no clinically significant or persistent dissociative symptoms.

In regard to substance use disorders, there is evidence that infusions of ketamine at subanesthetic doses improved motivation to quit and reduced cue-induced craving in nondepressed cocaine-dependent volunteers ([Dakwar et al. 2014](#)). Efforts to enhance a patient's motivation for change have been previously recognized as an important aspect of addiction-oriented psychotherapy, but this particular use of ketamine marks one of the first times that the psychological parameter of motivation has been targeted as a focus of pharmacotherapy.

In the realm of experimental psychopharmacology, ketamine has been explored as a safe research tool to transiently induce or provoke multidimensional schizophrenia-like symptoms ([Anticevic et al. 2012](#); [Lahti et al. 1995](#); [Perry et al. 2007](#)). Models of psychosis based on acute or chronic administration of noncompetitive NMDA receptor antagonists in both humans and rats show phenomenological validity with promise for testing new substances with potential antipsychotic effects ([Bubeníková-Valesová et al. 2008](#)). It is important to note that these uses are investigational as of the time of this writing (2015).

---

## Side Effects and Toxicology

---

Ketamine has a wide margin of safety but may be associated with various adverse reactions. At anesthetic doses of the drug (1–3 mg/kg), emergence reactions—characterized by a range of psychological manifestations including

hallucinations, confusion, delirium, vivid imagery, and a prolonged dreamlike state—have occurred in approximately 12% of patients recovering from anesthesia ([Green et al. 2011](#)). Other common side effects ( $\leq 10\%$ ) include transient nystagmus, diplopia, hypertension, tachycardia, respiratory stimulation, nausea, vomiting, and skin inflammation or rash. Less common side effects ( $\leq 1\%$ ) include anorexia, bradycardia, cardiac arrhythmia, hypotension, and respiratory depression. In rare cases ( $\leq 0.1\%$ ), anaphylaxis, sialorrhea, laryngospasm, and cystitis have been reported. Ketamine-induced renal dysfunction, ulcerative cystitis, and abdominal pain seem to be more prevalent in frequent, high-dose users ([Morgan and Curran 2012](#)).

At the subanesthetic doses (0.1–1 mg/kg) used in studies investigating ketamine's analgesic and antidepressant properties, cardiovascular and respiratory effects, including stimulation of the cardiovascular system and mild respiratory depression, have been demonstrated; therefore, adequate monitoring and medical support must be provided during administration. There is also evidence for mild, acute neuropsychiatric effects—such as neurocognitive disturbance, sensory-motor disturbance, and dissociation—that should be considered alongside preclinical data suggesting that ketamine may be neurotoxic in certain contexts, based on timing of administration, dosage given, and extent of exposure ([Krystal et al. 1994](#); [Malhotra et al. 1996](#); [Morgan et al. 2004](#); [Newcomer et al. 1999](#); [Soriano 2012](#)). It is significant that longer-term follow-up data do not report the persistent dissociative or psychotomimetic sequelae that previously were a concern regarding ketamine's use in depression, but further study of chronic-use outcomes is warranted, especially in the context of repeated medical use of ketamine ([Green and Li 2000](#); [Wan](#)

[et al. 2015](#)). For example, although studies of ketamine in mood disorder patients indicate that repeated infusions are largely well tolerated, studies in ketamine abusers and rodent models have pointed to adverse effects on brain structure and function under certain conditions of chronic exposure ([Liao et al. 2011](#); [Schobel et al. 2013](#); [C. Wang et al. 2013](#)).

Ketamine dependence has also been reported in the scientific literature, and the drug's potential for misuse and addiction may be related to its agonist activity at mu opioid receptors and/or to its dopaminergic effects ([Lindefors et al. 1997](#); [Liu et al. 2015](#); [Sanacora and Schatzberg 2015](#); [Xu and Lipsky 2015](#)). A valuable case report from *American Journal of Psychiatry* described the misuse and unintended consequences of ketamine prescribed for depression in a patient with a history of substance abuse before an optimized treatment plan and system of monitoring were put into place ([Schak et al. 2016](#)). Taken together, these initial findings suggest that although subanesthetic doses of ketamine administered to unipolar depressed patients in a controlled research setting present a low and acceptable level of risk, great emphasis must be placed on ongoing investigation regarding the abuse potential of ketamine, carefully regulated prescribing of ketamine for off-label use, and close follow-up and outcome reporting.

## Drug-Drug Interactions

---

Drugs such as rifampin and St. John's wort (which are potent inducers of CYP3A4) increase the metabolism and clearance of ketamine—and, to a much greater extent, of

norketamine ([Mion and Villevieille 2013](#)). Enzyme-inhibiting substances have the opposite effect and include clarithromycin and grapefruit juice (CYP3A4 inhibitors) and ticlopidine (a potent CYP2C19 inhibitor and a weak CYP2B6 inhibitor) ([Domino et al. 1984](#)). Several studies have also reported ketamine's synergistic effects when administered with other sedatives ([Akhavanakbari et al. 2014](#); [Eker et al. 2011](#); [Hui et al. 1995](#); [Lo and Cumming 1975](#)). The clinical relevance of these interactions remains unclear.

## Conclusion

---

Whereas much is known about the pharmacological profile of ketamine from its long history of use as an anesthetic and analgesic agent, far less is known about the mechanisms associated with ketamine's antidepressant efficacy at subanesthetic doses. Early studies implicated a number of pathways that may be involved in the therapeutic effects of ketamine, including pathways mediated by BDNF, TrkB, mTOR, and AMPA. Further investigations of NMDA receptor activity and the efficacy of other potential glutamate-modulating agents are ongoing. Therefore, as the use of ketamine in clinical practice becomes increasingly more common in U.S. hospital and clinic-based settings, it is imperative that the field develop standard operating procedures to guide clinical use. Despite the promise shown in initial trials of ketamine, it is important to recognize that ketamine therapy is still an experimental approach. The transient nature of ketamine's antidepressant activity and its potential for abuse suggest that routine adoption of this drug in psychiatric practice settings may be premature at

this time. Future research will need to work toward improving our understanding of ketamine's mechanism of action, developing administration strategies that offer sustained therapeutic benefit, and providing continued longitudinal assessment of safety and tolerability.

## CHAPTER 22

# Benzodiazepines

David V. Sheehan, M.D., M.B.A.

### History and Discovery

---

In spite of adverse publicity and a problematic public image, the most widely prescribed psychiatric medication in the United States over the past two decades is not an antidepressant, an atypical antipsychotic, or a mood stabilizer, but the benzodiazepine alprazolam, with more than 48 million prescriptions issued in 2013 (see [Grohol 2015](#); [Stahl 2002](#)).

The first benzodiazepine, chlordiazepoxide, was patented in 1959. Diazepam was introduced in 1963, and numerous derivatives of this drug have since been introduced into the market. The triazolobenzodiazepine alprazolam was introduced in 1981 and revolutionized the treatment of anxiety disorders when it was shown to be effective in the treatment of panic disorder ([Chouinard et al. 1982](#); [Sheehan et al. 1982](#)). It was the first benzodiazepine to be approved by the U.S. Food and Drug Administration (FDA) for the treatment of panic disorder. Since then, clonazepam, another high-potency benzodiazepine, also has received approval from the FDA for the treatment of panic disorder.

Benzodiazepines were widely prescribed in the 1960s, 1970s, and 1980s for pathological anxiety by psychiatrists, family practitioners, and internists who knew the drugs were effective and relatively safe when compared with prior anxiolytic medications such as the barbiturates and meprobamate. However, since the 1990s, selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) have displaced benzodiazepines as the clinician's first choice for the treatment of anxiety disorders ([Kramer 1993](#)). The SSRIs and SNRIs are safer and better tolerated than the tricyclic antidepressants and have been shown to be efficacious in a number of different anxiety disorders. In addition, they do not have the dependence, withdrawal, alcohol interaction, and abuse liability of the benzodiazepines.

Despite these drawbacks, benzodiazepines are often used as an adjunctive treatment with an SSRI or SNRI or as the primary treatment for the patient with no response or only a partial response to the SSRI or SNRI. The net result is only a small decline in the recommendation for a benzodiazepine ([Uhlenhuth et al. 1999](#)). One user in four uses the benzodiazepine for a year or longer. Among those using it as a hypnotic, 14% reported long-term use ([Balter 1991](#)). Rates of use increase with age, from 2.6% among

those 18-35 years to 8.7% among those 65-80 years ([Olson et al. 2015](#)). In recent years, there has been a shift to the use of short-half-life benzodiazepines.

---

## Structure-Activity Relations

---

Currently marketed benzodiazepines are similar in that they have the 1,4-benzodiazepine ring system. Modification of this ring system results in benzodiazepines with somewhat different properties ([Figure 22-1](#)).

## Pharmacokinetics and Disposition

Knowledge of benzodiazepine pharmacokinetics helps the clinician choose the most appropriate benzodiazepine for the patient and also guides its correct use. Benzodiazepines differ in their pharmacokinetic properties, such as absorption, distribution, and elimination (Table 22-1). On the other hand, all benzodiazepines are similar in that to some degree they all possess anxiolytic, muscle-relaxant, sedative-hypnotic, and anticonvulsant properties. The belief that one benzodiazepine is primarily anxiolytic while another is primarily hypnotic is not based on scientific evidence (Greenblatt et al. 1983a, 1983b). The preferential selection of a benzodiazepine for one market over another is usually dictated by its pharmacokinetic properties.

## Rate of Absorption

Benzodiazepines that are rapidly absorbed from the gastrointestinal tract enter and peak in the circulation quickly and have a quicker onset of action than those that are absorbed more slowly. Diazepam and clorazepate are rapidly absorbed and act quickly, chlordiazepoxide and lorazepam have intermediate rates of absorption and onset of action, and prazepam is slowly absorbed and has a slower onset of action.

Gastrointestinal absorption of benzodiazepines is dictated by intrinsic physiochemical properties of the drug and characteristics of the formulation such as particle size (Greenblatt et al. 1983a, 1983b). Benzodiazepine absorption when given intramuscularly is dictated by other factors. For example, chlordiazepoxide and lorazepam, when given orally, are absorbed at similar rates in the gastrointestinal tract. When given intramuscularly, lorazepam is more reliably, rapidly, and completely absorbed than chlordiazepoxide (Greenblatt et al. 1979, 1982b, 1983a, 1983b).

## Lipophilicity

The lipid solubility (lipophilicity) of a benzodiazepine at physiological pH influences the rate at which it crosses the blood-brain barrier by passive diffusion from the circulation, and this, in turn, determines the rapidity of onset of action and intensity of effect (Greenblatt et al. 1983a, 1983b). Highly lipophilic drugs cross the blood-brain barrier rapidly, and although all benzodiazepines are highly lipophilic, they differ in their degree of lipophilicity. Because diazepam is more lipophilic than lorazepam or chlordiazepoxide, it provides more rapid anxiety reduction and onset of side effects.

## Duration of Action

With benzodiazepines, the duration of therapeutic action is determined mainly by the rate and extent of drug distribution rather than by the rate of elimination. Benzodiazepine distribution is largely determined by its lipophilicity. Diazepam, which has a longer half-life than lorazepam, has a shorter duration of clinical action after a single dose. The reason for this is that diazepam, because of its greater lipid solubility, is more extensively distributed to peripheral sites, particularly to fat tissue. Consequently, it is more rapidly moved out of the blood and brain into inactive storage sites, and its

central nervous system (CNS) effects end more rapidly. Conversely, less lipophilic benzodiazepines maintain their effective brain concentrations longer because they are less extensively distributed to the periphery ([Greenblatt et al. 1983a, 1983b](#)).

## Rate of Elimination

The rate of elimination (elimination half-life) influences the speed and extent of accumulation and the time to reach a steady state. It also influences the time for drug washout after termination of multiple doses. Accumulation is slow and extensive when the half-life is long. When the rate of metabolic removal equals the rate of ingestion, the drug is said to have reached steady state. A useful rule of thumb is that when treatment has been in progress for at least four to five times as long as the elimination half-life, then the accumulation process is more than 90% complete ([Greenblatt et al. 1983a, 1983b](#)). When drugs with long elimination half-lives are stopped, they are washed out slowly, and the symptoms recur gradually over a period of days, with less intense or sudden rebound phenomena ([Greenblatt et al. 1981, 1982a; Kales et al. 1982](#)). Side effects from long-term treatment with long-half-life benzodiazepines last longer than with short-half-life benzodiazepines. Because of greater drug accumulation with long-half-life benzodiazepines, frequent drowsiness and sedation are a theoretical concern ([Greenblatt et al. 1981](#)). Tolerance to sedation occurs with long-term use, even though the plasma drug level remains the same. However, as a matter of caution, it is prudent to choose a benzodiazepine with a shorter or intermediate half-life for the elderly ([Greenblatt et al. 1982c](#)), individuals operating heavy machinery, and those engaging in high-level intellectual tasks.

## Biotransformation Pathway

Benzodiazepines are metabolized in the liver by microsomal oxidation or by glucuronide conjugation. Hepatic disease, age, several medical illnesses, and a number of drugs that impair oxidizing capacity, such as cimetidine, estrogens, and the hydrazine monoamine oxidase inhibitors (MAOIs), all influence the oxidation pathway. These factors usually magnify the side effects of the benzodiazepine. Consequently, in the elderly and in individuals with liver disease, benzodiazepines that are conjugated (e.g., temazepam, oxazepam, and lorazepam) are safer than benzodiazepines that are metabolized by oxidation (e.g., diazepam and alprazolam).

## Dosing: Sustained-Release Formulations

Dosing schedules of benzodiazepines should be dictated by knowledge about the rate of distribution rather than by information about elimination half-life. Sustained-release formulations of several benzodiazepines have been introduced to provide 24 hours of anxiolysis. In our experience, the sustained-release forms of alprazolam, clorazepate, diazepam, and adinazolam have a duration of therapeutic action of approximately 12 hours, not 24 hours. Standard alprazolam has a duration of action of 4–6 hours, clonazepam has a duration of action of 7 hours, and other standard-formulation benzodiazepines are within this 4- to 7-hour range.

---

## Mechanism of Action

---

Benzodiazepines produce anxiolysis by their effect on the  $\gamma$ -aminobutyric acid (GABA)-benzodiazepine receptor complex. GABA is synthesized from glutamic acid, which is also the most abundant free amino acid in the CNS. Like serotonin, norepinephrine, and dopamine neurons, the presynaptic GABA neuron has a reuptake pump that transports GABA from the synapse for storage or destruction by GABA transaminase. GABA has three target receptors: GABA<sub>A</sub>, GABA<sub>B</sub>, and GABA<sub>C</sub>. The chloride ion channel is controlled by GABA<sub>A</sub>.

Four distinct pharmacological properties have been described for the benzodiazepine receptor: anxiolytic, hypnotic, anticonvulsant, and muscle relaxation effects. GABA<sub>A</sub> receptors with  $\alpha_2$  (and/or  $\alpha_3$ ) subunits mediate the anxiolytic effects, whereas GABA<sub>A</sub> receptors with an  $\alpha_1$  subunit mediate the sedative-hypnotic actions. Most benzodiazepines interact with both these receptor subtypes. Typically, when GABA occupies the GABA<sub>A</sub> receptor site, opening and closing of the chloride channel occur more frequently, and this effect is inhibitory. If at the same time a benzodiazepine binds to the nearby benzodiazepine receptor, the GABA<sub>A</sub> receptor is allosterically modulated, and GABA exerts a greater effect (greater frequency of opening and closing) on the chloride channel and conductance. Although GABA works alone at the GABA receptor, the action of GABA is stronger in the presence of a benzodiazepine. The benzodiazepine in the absence of GABA cannot influence the chloride channel by itself.

---

## Therapeutic Uses

---

Because of their multiple pharmacological actions, benzodiazepines are useful in many areas of medical practice, such as induction of anesthesia, use as a muscle relaxant, and control of seizures. It is beyond the scope of this chapter to elaborate on these nonpsychiatric uses. In psychiatry, benzodiazepines are used to control anxiety, to treat insomnia, and to acutely manage agitation and withdrawal syndromes.

In the treatment of anxiety disorders, benzodiazepines have a greater effect in some disorders than in others. In panic disorder, they have a significant effect on all dimensions of the illness, with the exception of depression. Alprazolam, for example, has been shown to be effective in panic disorder at a mean dosage of 5.7 mg/day (range=1–10 mg/day) ([Ballenger et al. 1988](#); [Chouinard et al. 1982](#); [Cross National Collaborative Panic Study 1992](#); [Sheehan et al. 1982, 1984, 1993](#)). Rapid improvement was seen within the first week in the form of decreased panic attacks, phobic fears and avoidance, anticipatory anxiety, and disability. These benefits were shown to persist during a follow-up period of 8 months ([Schweizer et al. 1993](#)). Efficacy also has been established for lorazepam ([Rickels and Schweizer 1986](#)) and clonazepam ([Pollack et al. 1993](#); [Tesar et al. 1991](#)). In the latter studies, clonazepam 2.5 mg/day was as effective and well tolerated as alprazolam 5.3 mg/day.

Despite the well-documented efficacy of benzodiazepines in panic disorder, they have been displaced in clinical practice by the SSRIs and SNRIs. However, some clinicians initiate treatment with both classes of drug simultaneously and then withdraw the benzodiazepine after 6 weeks. The benefits and practicality of this approach to treating

panic disorder are reinforced by the findings from two studies ([Goddard et al. 2001, 2008](#)). The [American Psychiatric Association \(1998\)](#) guidelines for the treatment of panic disorder recommending SSRI monotherapy as the treatment of first choice have failed to achieve traction, because more than two-thirds of the SSRI prescriptions were accompanied by a concomitant benzodiazepine ([Keller and Craske 2008](#)). The study by [Goddard et al. \(2008\)](#) lends justification to the rationale for using the combination treatment more frequently and blessing it as a reasonable alternative first-line treatment for many patients with panic disorder.

Three double-blind studies have shown efficacy for benzodiazepines in the treatment of social phobia ([Davidson et al. 1993](#); [Gelernter et al. 1991](#); [Versiani et al. 1997](#)).

In a double-blind, placebo-controlled study, [Rickels et al. \(1993\)](#) found that the tricyclic antidepressant imipramine was better than diazepam in the treatment of generalized anxiety disorder (GAD) without depression over 8 weeks. Imipramine showed a trend of being significantly better on the primary outcome measure scale (the Hamilton Anxiety Scale [Ham-A]) and was statistically superior to diazepam on the Psychic Anxiety factor of the Ham-A. Psychic anxiety includes the items of worry, anxious mood, tension, fears, and concentration problems. Diazepam and imipramine had identical endpoint Ham-A Somatic Anxiety factor scores, suggesting that they are equally effective against the somatic anxiety symptoms in GAD. This suggests that imipramine is a better “anti-worry” medication than the benzodiazepine. Patients taking diazepam had an earlier response than those taking imipramine.

Generally, benzodiazepines are thought to be ineffective in the treatment of obsessive-compulsive disorder (OCD).

The strongest evidence for effective pharmacotherapy in posttraumatic stress disorder (PTSD) is with SSRIs. A meta-analysis of medications in treating PTSD found effect sizes of 0.49 and 1.38 for benzodiazepines and SSRIs, respectively ([Van Etten and Taylor 1998](#)).

Intramuscular clonazepam has been compared with intramuscular haloperidol in the management of acute psychotic agitation. Clonazepam use reduced agitation, but haloperidol use had a more rapid onset ([Chouinard et al. 1993](#)). Individuals with schizophrenia have high levels of anxiety and frequently experience panic attacks. Overall, it appears that benzodiazepines have a role in the acute management of agitation, and their use can reduce the need for or the dose of antipsychotics used.

---

## Side Effects and Toxicology

---

Benzodiazepines are among the safest of drugs, but unwanted effects do occur. The first 1,4-benzodiazepines, such as diazepam and flurazepam, had slow rates of elimination and low receptor-binding affinities. Their main side effect was excessive daytime sleepiness. The late 1970s saw the introduction of the 1,4-benzodiazepines flunitrazepam and lorazepam, which had shorter half-lives and were more potent. These drugs were associated with enhanced efficacy but also with more rapid development of tolerance and significant withdrawal problems. The triazolobenzodiazepines were introduced in the 1980s and were even more potent and had even shorter half-lives. They also have been found to be associated with amnesia, daytime anxiety, early-morning insomnia, and withdrawal problems such as rebound insomnia, anxiety, and seizures ([Noyes et al. 1986](#)).

Sedation and drowsiness are common, occurring in 4%–9% of patients taking benzodiazepines. Ataxia occurs in up to 2%. The drowsiness tends to disappear with time or a reduction in dose ([Greenblatt et al. 1982b](#); [Miller 1973](#); [Svenson and Hamilton 1966](#)). Benzodiazepines may impair psychomotor performance. Most benzodiazepines, shortly after administration at their peak concentration, cause anterograde amnesia ([Lister et al. 1988](#)). These effects are dependent on potency and route of administration ([Bixler et al. 1979](#)). Overall, this memory impairment does appear to be independent of the degree of sedation produced by the drug ([Scharf et al. 1988](#)). Benzodiazepine-treated subjects are often unaware of or underestimate the extent of their memory impairment ([Roache and Griffiths 1985, 1987](#)).

Hyperexcitability phenomena such as early-morning awakening and rebound anxiety and nervousness are more likely with the short-half-life, high-potency benzodiazepines such as triazolam, alprazolam, lorazepam, and brotizolam ([Kales et al. 1983, 1986, 1987](#); [Vela-Bueno et al. 1983](#)). Treatment-emergent hostility ([Rosenbaum et al. 1984](#)) may be seen in up to 10% of the patients receiving benzodiazepines. This is most likely to happen early in treatment, is unrelated to pretreatment impulsivity, and has been reported with all benzodiazepines with the exception of oxazepam. Treatment-emergent mania has been reported with alprazolam ([Goodman and Charney 1987](#); [Pecknold and Fleury 1986](#); [Strahan et al. 1985](#)).

Since the 1960s, benzodiazepines have been known to produce anterograde amnesia, even with oral dosing ([Lister 1985](#)). The deficit is one of disrupted consolidation and not impairment of memory retrieval. The degree of amnesia can range from minimal inability to retain isolated pieces of information to total inability to recall any activities that occurred during a specific period. Whether some benzodiazepines are more likely than others to produce amnesia remains an unresolved question.

## Cognitive Impairment and Risk of Alzheimer's Disease

Some publications have raised concerns that the long-term use of benzodiazepines may lead to cognitive and other impairments that persist long after the drugs have been discontinued. Abnormal computed tomography (CT) scans were reported in long-term users of benzodiazepines in one study ([Lader et al. 1984](#)) but not in others ([Poser et al. 1983](#); [Rickels 1985](#)). [Busto et al. \(2000\)](#) found no difference in the CT brain scans of patients taking benzodiazepines compared with control subjects. Long-term benzodiazepine users have been compared with control subjects and found to have cognitive impairments that reversed on reexamination after taper ([Golombok et al. 1988](#); [Lucki et al. 1986](#); [Rickels et al. 1999](#); [Sakol and Power 1988](#)). Another study found that after long-term use, if the benzodiazepine was stopped, there was only partial recovery even after 6 months ([Tata et al. 1994](#)).

[Billioti de Gage et al. \(2014\)](#) reported inferential evidence suggesting that the use of benzodiazepines for longer than 3 months may be associated with an increased risk for Alzheimer's disease. They used a case-control design to minimize sampling bias and sampled subjects 6 years before the official diagnosis of Alzheimer's disease in an attempt to control for "reverse bias" (the possibility that Alzheimer's disease resulted in benzodiazepines being used before the onset of the dementia). [Salzman and Shader \(2015\)](#) wrote a rejoinder to this study highlighting its methodological limitations and offering alternative interpretations for the findings. They pointed out that the results "could be interpreted to suggest that benzodiazepine use does not cause increased

Alzheimer's disease, but Alzheimer's disease causes an increased need for benzodiazepine treatment in some patients" (p. 2), notably for the prodromal anxiety and insomnia so frequently associated with this illness. In their editorial, [Balon et al. \(2015\)](#) urged caution in the interpretation of the results and noted that it was "premature to conclude that benzodiazepines are a causative factor in a multidimensional disorder such as Alzheimer's disease" ([Balon et al. 2015](#), p. 244).

[Pariente et al. \(2016\)](#) reviewed the literature on the association between benzodiazepine use and the risk of dementia disorders. Nine of the 11 studies reported a harmful effect; 1 study reported a protective effect; and the most recent, largest, best-controlled, and most prospectively designed study found no effect. The problem in interpreting a finding of any such association in an inadequately controlled meta-analytic study is that both anxiety and sleep disturbances are common prodromal symptoms in dementia. A lack of adequate controls confounds the interpretation of results in these studies.

The most recent *BMJ* study ([Gray et al. 2016](#)) followed 3,434 adults ages 65 years and older for 7 years. None had dementia at study initiation; 23% developed dementia by the end of the study. Gray and colleagues used computerized pharmacy data to assess benzodiazepine use. They found no link between the highest level of benzodiazepine use (on average, 1 year of daily use) and dementia or cognitive decline. A small increased risk for dementia was seen in people with moderate (1–4 months) and low (up to 1 month) levels of benzodiazepine use but not in those using benzodiazepines for longer than 4 months. The authors concluded that the pattern of findings "does not support the theory that cumulative benzodiazepine use at the levels observed in our population is causally related to an increased risk for dementia or cognitive decline" ([Gray et al. 2016](#)).

Practice guidelines recommend that benzodiazepines be avoided in Alzheimer's disease and restricted to short-term, as-needed use in elderly persons ([Madhusoodanan and Bogunovic 2004](#); [Salzman 1990](#)). That said, others may agree with the comment by [Salzman and Shader \(2015\)](#), both very seasoned and knowledgeable psychopharmacologists, that

experienced geriatric clinicians often find that judicious use of low-dose, short half-life BZs reduces stress, promotes daytime functioning, and assists in sleep onset; elderly patients themselves report that they would gladly forgo short-term memory reduction in exchange for a calmer daytime and reliable sleep onset.  
(p. 2)

## Drug-Drug Interactions

---

Antacids slow benzodiazepine absorption, because aluminum delays gastric emptying ([Greenblatt et al. 1983a](#), 1983b). An acid medium is needed for conversion of clorazepate to desmethyldiazepam, the active metabolite, which is then absorbed ([Shader et al. 1978](#)).

In the liver, benzodiazepines are metabolized by oxidation, reduction, or conjugation. Alprazolam, diazepam, clorazepate, prazepam, chlordiazepoxide, bromazepam, and halazepam are metabolized by oxidation; nitrazepam by reduction; and lorazepam, oxazepam, and temazepam by conjugation. Inhibitors of the oxidase system prolong the half-life of benzodiazepines that are metabolized by this system. This accentuates the

side effects, notably the sedation, ataxia, slurred speech, and imbalance. A decrease in dosage may solve this problem, or a switch to a benzodiazepine that is metabolized by conjugation may be needed. MAOIs, cimetidine ([Greenblatt et al. 1984](#)), and oral contraceptives inhibit the oxidative system. A decline in this system occurs with age or liver disease. In the elderly, there is a 50% decrease in clearance, with a four- to ninefold increase in half-life and a two- to fourfold increase in the volume of distribution ([Peppers 1996](#)). Heparinized patients ([Routledge et al. 1980](#)) should have partial thromboplastin time (PTT) monitored more closely, because PTT is prolonged by benzodiazepines. Because antidepressants such as fluoxetine, paroxetine, and nefazodone and protease inhibitors such as indinavir sulfate inhibit the cytochrome P450 enzyme 3A4, they inhibit the metabolism of triazolobenzodiazepines such as midazolam, alprazolam, and triazolam.

---

## Clinical Issues

---

Despite decades of research, the optimal extent and duration of appropriate benzodiazepine use in the treatment of anxiety and related disorders remain unresolved. This is primarily because of concerns expressed by prescribers, regulators, and the public about issues such as tolerance, dependence, and abuse liability of this class of medications.

### Tolerance

In a study of persistent users of alprazolam and lorazepam, [Romach et al. \(1995\)](#) found that most were not abusing these benzodiazepines, nor were they addicted to them; rather, they were using them appropriately for a chronic disorder and at a constant or a decreasing dose. [Soumerai et al. \(2003\)](#) found no relation between long-term use of benzodiazepines and escalation to high doses in 2,440 long-term (at least 2 years) users of benzodiazepines and noted that escalation to a high dose was very rare.

The cross-tolerance between the benzodiazepines, although good, is not perfect, and it is preferable to switch patients gradually from one benzodiazepine to another and to use comparable doses of each during the switch. One milligram of alprazolam is approximately equivalent to 0.7 mg of clonazepam, 10 mg of diazepam, or 1 mg of lorazepam.

### Withdrawal

A withdrawal syndrome is defined as a predictable constellation of signs and symptoms involving altered CNS activity (e.g., tremor, convulsions, or delirium) after the abrupt discontinuation of, or a rapid decrease in, dosing of the drug ([Rinaldi et al. 1988](#)). Typically, a withdrawal syndrome from short-half-life benzodiazepines will intensify by the second day, will usually have peaked by day 5, and will begin to decrease and taper off by day 10. After 2 weeks, withdrawal symptoms usually have become minimal or are absent. Drug factors associated with withdrawal symptoms include length of use, dose, potency, and rate of discontinuation. The most common are anxiety, restlessness, irritability, insomnia, agitation, muscle tension, weakness, aches and pains, blurred

vision, and racing heart, in that order (O'Brien 2005). Nausea, sweating, runny nose, hypersensitivity to stimuli, and tremor are less frequent. Severe withdrawal symptoms, such as psychosis, seizures, hallucinations, paranoid delusions, and persistent tinnitus, are relatively rare and are more likely to occur in abrupt withdrawal from high doses of high-potency benzodiazepines and in the elderly (American Psychiatric Association 1990; Lader 1990; Petursson and Lader 1981).

The minimum duration of use after which clinically significant withdrawal symptoms can be expected has not been definitively determined. At the end of any course of treatment with therapeutic doses and of duration greater than 3–6 weeks, withdrawal of the benzodiazepine should be done as a very slow taper. This reduces the risk of unpleasant withdrawal symptoms and the danger of withdrawal seizures and minimizes rebound reactivation of the underlying anxiety disorder (Fontaine et al. 1984; Pecknold et al. 1988; Power et al. 1985).

In a 3-year follow-up of patients who tapered successfully in a benzodiazepine taper program, 73% remained benzodiazepine free. Among those who were able to reduce intake by 50%, only 39% were benzodiazepine free at the end of 3 years. In the group that could not tolerate taper at all, only 14% were benzodiazepine free (Rickels et al. 1991).

## Addiction Potential

In our zeal to heal an anxiety disorder, are we creating a population of addicted individuals? Much misinformation and concern are generated because terms like *addiction* are used without precise definition and pejoratively. Terms such as *addiction*, *physical dependency*, and *withdrawal syndrome* are often used interchangeably. Some presume that a medicine's being associated with a withdrawal syndrome is evidence that the medicine is addicting. Some clinicians believe that benzodiazepines that require frequent dosing during the day are more addicting than those that require less frequent dosing. In reality, frequency of dosing is a function of the duration of therapeutic action of the drug rather than of any innate addiction potential of the drug.

Most of the literature discussing benzodiazepine dependence liability uses older terminology. *Substance dependence* is defined as a maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by the presence of three (or more) of seven criteria, occurring at any time in the same 12-month period (American Psychiatric Association 2000). *Addiction*, by contrast, is defined as a chronic disorder associated with compulsive use of a drug, resulting in physical, psychological, or social harm to the user and continued use despite that harm (Rinaldi et al. 1988). Addiction involves both intense drug-seeking behavior and difficulty in stopping the drug use. If these criteria are used, benzodiazepines are not addictive drugs. *Physical dependence* is different from addiction and is defined as a physiological state of adaptation to a drug, with the development of tolerance to the drug's effects and the emergence of a withdrawal syndrome during prolonged abstinence. During withdrawal after chronic use, biochemical, physiological, or behavioral problems may be triggered. When used on a regular schedule, benzodiazepines are associated with physical dependence and have a withdrawal syndrome.

In DSM-5 (American Psychiatric Association 2013), the terms *abuse* and *dependence* are no longer used in relation to substances. Instead, DSM-5 uses the more neutral term *substance use disorder* to capture the wider range of disorders previously

subsumed under *substance dependence* and *substance abuse*. DSM-5 also uses the terms *substance intoxication* and *substance withdrawal*. *Substance use disorder* is defined as a problematic pattern of substance use leading to clinically significant impairment or distress, as manifested by the presence of 2 (or more) of either 10 or 11 criteria, occurring within a 12-month period. At this time, no large epidemiological studies have used these new criteria in relation to benzodiazepines.

## Abuse

Studies of abuse use four criteria for benzodiazepine abuse. A benzodiazepine is being abused if it is used 1) to get high, 2) to promote psychological regression, 3) at doses higher than prescribed, and 4) after the medical indication has passed ([Dietch 1983](#)). On the basis of this definition, the data suggest that the incidence of benzodiazepine abuse in clinical practice is low.

The incidence of benzodiazepine dependence in the therapeutic setting (among those for whom the drug is medically correctly prescribed) was estimated to be 1 case in 50 million patient-months ([Marks 1978](#)). Of these cases, 92% were associated with alcohol or other drugs of abuse. This estimate is probably on the low side because it is based on the number of published cases of dependence from 1961 to 1977.

In Basel, Switzerland, with a catchment area of 300,000 people, physicians were surveyed on the prevalence of benzodiazepine abuse in their patients. Only 31 patients were identified—a prevalence of 0.01%, or 1 in 10,000. An additional 88 polysubstance abusers were identified ([Ladewig and Grossenbacher 1988](#)). In a random sample of all psychiatric hospitalizations over 15 years (1967–1983) in Sweden ( $N=32,679$ ), [Allgulander \(1989\)](#) found only 38 admissions for substance dependence on sedative-hypnotics. Twenty-one of the 38 had polysubstance abuse, and 17 had sedative-hypnotic abuse.

In another study of all medical and psychiatric hospitalizations ( $N=1.6$  million) in Stockholm County, Sweden, [Allgulander \(1996\)](#) found that 0.04% of “prescribed medication” users (including benzodiazepines) were ever admitted for medical problems relating to their drug use. In a study of 5,426 U.S. physicians randomly selected from the American Medical Association Physician Masterfile database, [Hughes et al. \(1992\)](#) found that although 11.9% had used benzodiazepines in the past year, only 0.6% met DSM-III-R ([American Psychiatric Association 1987](#)) criteria for benzodiazepine abuse, and 0.5% met criteria for benzodiazepine dependence. In 1990, the American Psychiatric Association task force concluded that benzodiazepines were not normally drugs of abuse but noted that people who abused alcohol, cocaine, and opiates were at increased risk for benzodiazepine abuse ([Salzman 1991](#)).

A number of studies have noted no increase in dosage with chronic therapy of duration from 1 to 2.5 years, even though many of the patients had residual symptoms that would have benefited from a dose increase or more intensive or additional treatment strategies ([Pollack et al. 1986](#); [Sheehan 1987](#)). Nonanxious subjects and those with low anxiety levels find benzodiazepines dysphoric ([Reed et al. 1965](#)), prefer placebo to diazepam ([Johanson and Uhlenhuth 1978, 1980](#)), or rate their mood as less happy and pleasant after they were given 10 mg of diazepam ([Svensson et al. 1980](#)).

Although the data suggest that the prevalence of benzodiazepine abuse or dependence is generally low, this is not true among those who abuse alcohol and other drugs. In a study of chronic alcoholic individuals who were high consumers of

benzodiazepines, 17% got their benzodiazepines from nonmedical sources ([Busto et al. 1983](#)). In a study of 1,000 admissions to an alcohol treatment unit, 35% of the patients used benzodiazepines, but only 10% of the total sample were considered abusers or misusers ([Ashley et al. 1978](#)). A study of 427 patients seeking treatment in Toronto, Ontario, who met DSM-III ([American Psychiatric Association 1980](#)) criteria for alcohol abuse or dependence found that 40% were recent benzodiazepine users, and 20% had a lifetime history of benzodiazepine abuse or dependence. By contrast, only 5% of 108 alcoholic patients treated for a year with benzodiazepines for anxiety and tension showed evidence of abuse, and 94% believed that the medication helped them function and remain out of the hospital ([Rothstein et al. 1976](#)).

Benzodiazepines were the primary drug of abuse in one-third of polydrug abusers ([Busto et al. 1986](#)), in 29% of 113 drug abusers admitting to the street purchase of diazepam in the previous month ([Woody et al. 1975b](#)), and in 40% of patients at a methadone maintenance clinic ([Woody et al. 1975a](#)). The principal reasons for benzodiazepine use among drug-addicted persons are self-treatment of withdrawal symptoms, relief from rebound dysphoria, or potentiation of alcohol or street drug effects ([Perera et al. 1987](#)). In one study at an addiction treatment center, 100% of urine samples tested were positive for benzodiazepines, and 44% were positive for multiple nonprescribed benzodiazepines ([Iguchi et al. 1993](#)). A survey of patients at three different methadone maintenance clinics found that 78%–94% admitted to a lifetime use of benzodiazepines, and 44%–66% admitted to use in the prior 6 months. Snorting of benzodiazepines by individuals addicted to cocaine has been reported ([Sheehan et al. 1991](#)), primarily as a means of blunting the anxiogenic effect of cocaine and allowing for a more pleasant and “less edgy” high from that drug. Overall, the existing evidence suggests that the prevalence of benzodiazepine abuse is uncommon, except among those individuals who abuse alcohol and/or other drugs.

Despite extensive data and discussion on this topic, the issue remains and will continue to be controversial, with strong opinions held by opposing camps. Klerman characterized these camps as “pharmacological Calvinism” and “psychotropic hedonism,” respectively ([Klerman 1972](#); [Rosenbaum 2005](#)). The middle ground suggests that we should not hesitate to prescribe benzodiazepines when it is reasonable, but that we should exercise restraint in using them when we see any evidence of abuse ([Pomeranz 2007](#)).

## Medicolegal Issues

---

In addition to issues of dependence and withdrawal described in the previous section, use of benzodiazepines is associated with several potential medicolegal pitfalls. These include issues of teratogenicity, injury, and interaction with substances.

## Benzodiazepines and Pregnancy

Because anxiety disorders have their highest incidence in women during their childbearing years, the clinician may have to advise patients who are planning a pregnancy or who become pregnant while taking a benzodiazepine.

## First and Second Trimesters

An important concern in the first and second trimesters is the possibility of teratogenic effects. Diazepam and desmethyldiazepam cross the placental barrier easily, and concentrations are higher in fetal blood than in maternal blood ([Idänpään-Heikkilä et al. 1971](#)). Early concern over benzodiazepine exposure in pregnancy arose because benzodiazepines act on GABA receptors, and GABA is involved in palate shelf reorientation ([Wee and Zimmerman 1983](#); [Zimmerman and Wee 1984](#)). The teratogenic effects of benzodiazepines, however, are a matter of controversy. Exposure to benzodiazepines has been associated with teratogenic effects, including facial clefts and skeletal anomalies in the newborn in some animal studies ([Miller and Becker 1975](#); [Walker and Patterson 1974](#); [Wee and Zimmerman 1983](#); [Zimmerman 1984](#); [Zimmerman and Wee 1984](#)) but not in others ([Beall 1972](#); [Chesley et al. 1991](#)). Early studies in humans, including retrospective and case-control studies, reported an increased risk of oral clefts associated with diazepam ([Aarskog 1975](#); [Livezey et al. 1986](#); [Safra and Oakley 1975](#); [Saxén 1975](#); [Saxén and Lahti 1974](#)). These results, however, have been criticized on methodological grounds and are contradicted by more recent prospective studies, case-control studies, and meta-analyses that show no increased risk of oral clefts related to benzodiazepine use in pregnancy ([Altshuler et al. 1996](#); [Bracken 1986](#); [Czeizel 1987–1988](#); [Dolovich et al. 1998](#); [Ornoy et al. 1998](#); [Pastuszak et al. 1996](#); [Rosenberg et al. 1983](#); [Shiono and Mills 1984](#)).

Pooled data from seven cohort studies, however, do not support an association between fetal exposure to benzodiazepines and major malformations ([Dolovich et al. 1998](#)).

## Third Trimester and Labor

Two concerns associated with benzodiazepine use in the last trimester and through delivery are the possibilities of CNS depression and a withdrawal syndrome. Signs of CNS depression may include hypotonia, lethargy, sucking difficulties, decreased fetal movements, loss of cardiac beat-to-beat variability, respiratory depression, and thermogenesis. These symptoms in the neonate are more likely with higher doses and longer duration of benzodiazepine use by the mother. There have been numerous reports of “floppy infant syndrome” in babies born to women taking diazepam long term during pregnancy ([Gillberg 1977](#); [Haram 1977](#); [Rowlatt 1978](#); [Speight 1977](#)). Neonatal withdrawal symptoms may include hyperactivity and irritability. The occurrence of neonatal withdrawal symptoms is well documented ([Barry and St Clair 1987](#); [Briggs et al. 1998](#); [Cree et al. 1973](#); [Fisher et al. 1985](#); [Gillberg 1977](#); [Haram 1977](#)). Symptoms may be present at birth or appear weeks later and may continue for a period of time ([Schardein 1993](#)).

Diazepam in isolated doses is safe during labor ([Briggs et al. 1998](#)). There are conflicting reports on the effect of benzodiazepines on Apgar scores. Lowered Apgar scores have been reported with benzodiazepine use in some studies ([Berdowitz et al. 1981](#); [McElhatton 1994](#)). One study found that diazepam reduced Apgar scores only when doses greater than 30 mg were administered during labor ([Cree et al. 1973](#)).

## Breast Feeding

Neonates have only limited capacity to metabolize diazepam ([Morselli et al. 1973](#)). Benzodiazepines are excreted in breast milk ([Llewellyn and Stowe 1998](#)). Because of

the neonate's limited capacity to metabolize these drugs, they can potentially accumulate and cause sedation, lethargy, and loss of weight in the nursing infant. Although the extent to which benzodiazepines actually accumulate in the serum of breast-feeding infants is a matter of debate ([Birnbaum et al. 1999](#)), and three decades of studies support a low incidence of toxicity and adverse effects ([Birnbaum et al. 1999](#); [Llewellyn and Stowe 1998](#)), caution taking benzodiazepines while breast feeding is advised.

## Psychomotor Impairment

Another area of risk of benzodiazepine use relates to issues of psychomotor impairment resulting in injury. An examination of the medical records of a group of benzodiazepine users and nonusers found that the benzodiazepine users were more likely to experience at least one episode of accident-related health care and a greater number of accident-related inpatient days and also utilized significantly more non-accident-related health care services than did nonusers. Accident-related utilization of health care was more likely in the first month after the drug was prescribed ([Oster et al. 1987](#)). In the elderly, the issue of benzodiazepine use increasing the risk for falls and fractures is of great concern because hip fractures are associated with increased morbidity and mortality. A number of studies ([Boston Collaborative Drug Surveillance Program 1973](#); [Cummings et al. 1995](#); [Greenblatt et al. 1977](#); [Hemmelgarn et al. 1997](#); [Ray et al. 1992](#); [Roth et al. 1980](#)) have found a greater risk for falls with the use of long-half-life benzodiazepines, and others ([Cumming and Klineberg 1993](#); [Herings et al. 1995](#); [Leipzig et al. 1999](#)) have found the risk to be greater with short-half-life drugs. A more recent study ([Wang et al. 2001](#)) found the risk for hip fracture in the elderly to be the same with the use of short- or long-half-life benzodiazepines. The researchers did find that the risk increased when benzodiazepine dosages were greater than 3 mg/day in diazepam equivalents. They also found the greatest risk to be shortly after initiation of therapy and after 1 month of continuous use. A 5-year prospective cohort study followed a large group of elderly people newly exposed to benzodiazepines ([Tamblyn et al. 2005](#)). Elderly persons using benzodiazepines were at greater risk for a motor vehicle accident ([Hemmelgarn et al. 1997](#)). On the other hand, a study of the effect of New York State requiring triplicate forms for prescribing benzodiazepines showed that despite a 50% decrease in the number of prescriptions written, no significant change was seen in age-adjusted risk for hip fractures ([Wagner et al. 2007](#)).

Patients receiving benzodiazepines are nearly five times more likely than nonusers to experience a serious motor vehicle accident ([Skegg et al. 1979](#)). In the first 2 weeks after persons start using benzodiazepines, there is a several-fold increased risk for hospitalization related to accidental injury compared with persons using antidepressants or antipsychotics ([Neutel 1995](#)).

The best protection is a discussion of these issues with the patient before prescribing a benzodiazepine. This discussion, including cautionary statements about driving or operating dangerous machinery, should be documented in the chart at the start of therapy. The patient should be educated about potentiation by alcohol or other sedating drugs. He or she should be strongly advised never to abruptly discontinue the medicine because of a risk of seizures ([Noyes et al. 1986](#)), and this should be documented. Prescribing benzodiazepines for patients with a current or lifetime history of substance abuse or dependence should be done infrequently and only after documenting a risk-

benefit discussion in the chart. It is good practice to routinely screen for substance abuse before prescribing a benzodiazepine and to document that this was done.

---

## Conclusion

---

Benzodiazepines, if given in adequate doses, are effective in the treatment of anxiety. They have a lower mortality and morbidity per million prescriptions than some of the alternatives (Girdwood 1974), including atypical antipsychotics. Benzodiazepines are quicker in onset of action, easier for the clinician to use, associated with better compliance, and less subjectively disruptive for the patient than any of the other medication alternatives. Until benzodiazepines are replaced by another class of medicine that is safer, better tolerated, and as rapidly effective, it is likely that they will continue to be prescribed to a significant proportion of patients.

# CHAPTER 23

## Buspirone

Donald S. Robinson, M.D.

Karl Rickels, M.D.

**Altered** central serotonergic function is implicated in several psychiatric disorders, especially mood and anxiety disorders. Discovery of the serotonin-1A (5-HT<sub>1A</sub>) receptor linked modulation of serotonin (5-hydroxytryptamine [5-HT]) neurotransmission to anxiety symptoms. Similarly, tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) linked serotonin to the pathophysiology and treatment of depression.

The notion of a role for serotonin in the treatment of anxiety arose from the finding that benzodiazepines reduce brain 5-HT turnover and that para-chlorophenylalanine (pCPA), an inhibitor of serotonin synthesis, mimics the effects of benzodiazepines in behavioral models of anxiety ([Wise et al. 1972](#)). Discovery of the 5-HT<sub>1A</sub> receptor partial agonist buspirone confirmed that serotonin plays a key role in anxiolysis ([Eison and Eison 1994](#)). Because both

benzodiazepines and buspirone reduce 5-HT impulse flow, albeit by different mechanisms, altered serotonergic tone was postulated to be an underlying factor in the etiology of anxiety disorders.

---

## The 5-HT<sub>1A</sub> Receptor

---

Identification of multiple serotonin receptors ([Hoyer et al. 2002](#); [Pierce et al. 2002](#)) and discovery of the role of the 5-HT<sub>1A</sub> receptor, which couples negatively to adenylyl cyclase ([De Vivo and Maayani 1986](#); [Savitz et al. 2009](#)), led to pharmacological characterization of this receptor utilizing selective agonists ([Hamon et al. 1984](#)); selective partial agonist azapirones, such as buspirone ([Figure 23-1](#)); and specific antagonists ([Fletcher et al. 1996](#)). Clinical development of 5-HT<sub>1A</sub> partial agonists, which were active in models of both anxiety and depression, ensued when it became apparent that this receptor plays a central role in neuropsychiatric disorders ([Robinson et al. 1989a](#)).

---

**FIGURE 23-1.** Chemical structure of buspirone.

## Pharmacological and Clinical Implications

High regional density of 5-HT<sub>1A</sub> receptors in midbrain, hippocampus, and limbic areas of the brain comports with the notion that 5-HT neurotransmission modulates mood and anxiety. Brain regions with high densities of 5-HT<sub>1A</sub> receptors control thermoregulation, endocrine function, appetite, aggressive and sexual behavior, and mood. Mice lacking the 5-HT<sub>1A</sub> receptor gene exhibit manifestations of anxious behavior ([Parks et al. 1998](#); [Pattij et al. 2002](#)).

5-HT<sub>1A</sub> receptors on 5-HT neurons in midbrain raphe regions modulate release of 5-HT at synapses in forebrain. These somatodendritic autoreceptors control synthesis and impulse flow ([Yocca 1990](#)) and release ([Sharp et al. 1989](#)) of neurotransmitter from ascending 5-HT-containing neurons. Using the receptor-specific, tritiated ligand 8-hydroxy-2-[*N*-dipropylamino]-tetralin (8-OH-DPAT), [Stockmeier et al. \(1998\)](#) reported enhanced binding of the ligand to inhibitory 5-HT<sub>1A</sub> autoreceptors in the dorsal raphe of suicide victims, in support of the hypothesis that these individuals had diminished 5-HT neuronal activity. Imaging studies of brain regions using OH-DPAT or the receptor-specific radioligand [carbonyl-<sup>11</sup>C]WAY100635 confirmed diminished function (reduced binding potential) of serotonin 5-HT<sub>1A</sub> receptors in the brains of both suicide victims and patients with major depressive disorder (MDD) compared with matched controls ([Boldrini et al. 2008](#); [Drevets et al. 2007](#); [Hirvonen et al. 2008](#); [Meltzer et al. 2004](#)), indicative of diminished activity of 5-HT neurons in mood disorders. Blunted 5-HT<sub>1A</sub> receptor-mediated response to corticosteroids is present in patients with MDD, suggesting desensitization of these receptors in patients with anxiety and depression ([Lesch 1992](#); [Rausch et al. 2006](#); [Stahl 1992](#)).

# 5-HT Receptors and Partial Agonists

Given the evidence implicating 5-HT in mood disorders and the role of the 5-HT<sub>1A</sub> receptor in 5-HT neurotransmission, drugs targeting this receptor hold interest for the treatment of mood and anxiety disorders. Partial agonists of this receptor act in part by signal attenuation at one or more target receptors ([Yocca and Altar 2006](#)). The partial agonist buspirone produces therapeutic response with an excellent safety profile and was developed for the treatment of anxiety and associated depression.

Although the selective 5-HT<sub>1A</sub> receptor partial agonist gepirone recently (May 2016) received U.S. Food and Drug Administration (FDA) approval for the treatment of MDD, no other selective 5-HT<sub>1A</sub> agonists have obtained FDA approval for a generalized anxiety disorder (GAD) indication. An appropriate degree of agonism at both pre- and postsynaptic 5-HT<sub>1A</sub> receptors may be essential for anxiolytic efficacy. There is a region-dependent difference in responses to 5-HT<sub>1A</sub> agonists at pre- and postsynaptic 5-HT<sub>1A</sub> receptors, possibly attributable to differences in regional receptor reserve ([Meller et al. 1990](#); [Yocca et al. 1992](#)).

---

## History and Development

---

Buspirone hydrochloride, an azaspirodecanedione derivative ([Wu et al. 1969](#)), was originally studied as a putative antipsychotic agent but was not efficacious ([Sathananthan et al. 1975](#)). Buspirone was found to produce a marked taming effect in aggressive monkeys

([Tompkins et al. 1980](#)). In behavioral rodent models of anxiety, buspirone inhibited footshock-induced fighting and prevented shock-induced suppression of drinking behavior, tests predictive of anxiolytic effects ([Riblet et al. 1982](#)). At that time, minimal data were available on the molecular pharmacology of buspirone, although it had been reported to displace [<sup>3</sup>H]spiperone from dopamine D<sub>2</sub> receptors in rat striatal membranes and to produce a right shift in binding activity in the presence of guanosine triphosphate (GTP), both characteristics of a D<sub>2</sub> agonist ([Riblet et al. 1982](#)). Until subsequent discovery of buspirone's high-affinity binding to the newly discovered 5-HT<sub>1A</sub> receptor, the anxiolytic activity of buspirone was presumed to be dopaminergic.

A Phase II proof-of-concept study in patients with DSM-II ([American Psychiatric Association 1968](#)) anxiety disorder showed significant anxiolytic efficacy of buspirone compared with placebo ([Goldberg and Finnerty 1979](#)), which fostered its clinical development as an antianxiety agent ([Robinson 1991](#)). Recently, buspirone was found to bind to dopamine D<sub>3</sub> and D<sub>4</sub> receptors, suggesting its possible utility in treatment of drug addiction ([Bergman et al. 2013](#); [Le Foll and Boileau 2013](#)).

---

## Pharmacological Profile

---

Buspirone has low affinity in vitro for noradrenergic, cholinergic, and histaminergic receptors and does not displace [<sup>3</sup>H]diazepam or [<sup>3</sup>H]nitrazepam from the benzodiazepine receptor complex ([Riblet et al. 1982](#)). Although buspirone displaces [<sup>3</sup>H]spiperone from rat

striatal membranes at high concentrations ([Mennini et al. 1986, 1987](#)), dopamine receptor binding appears to play no role in either the therapeutic effects or the side effects of buspirone ([Eison et al. 1991](#)). In the frontal cortex of freely moving rats, buspirone produces dose-dependent decreases in dialysate levels of 5-HT and increases in levels of dopamine and norepinephrine, findings indicative of multiple mechanisms by which buspirone may modify monoaminergic neurotransmission ([Gobert et al. 1999](#)).

The discovery that nanomolar quantities of buspirone displaced [<sup>3</sup>H]5-HT from hippocampal membranes ([Glaser and Traber 1983](#)) led to elucidation of buspirone's actions on specific central 5-HT receptors. Buspirone inhibits [<sup>3</sup>H]5-HT binding to cortical and hippocampal membranes ([Skolnick et al. 1985](#)) and selectively displaces [<sup>3</sup>H]8-OH-DPAT from 5-HT<sub>1A</sub> receptor-binding sites in rat hippocampal membranes with high affinity (24 nM) ([Yocca 1990](#)).

The antianxiety properties of buspirone reflect its actions at both pre- and postsynaptic 5-HT<sub>1A</sub> receptors ([Eison and Eison 1994](#); [Yocca 1990](#)). At presynaptic 5-HT<sub>1A</sub> receptors in the dorsal raphe, buspirone acts as a full agonist, inhibiting neuronal 5-HT synthesis and firing, whereas at postsynaptic receptors in hippocampus and cortex, it functions as a partial agonist. It is postulated that the anxiolytic effect of buspirone is mediated by serotonergic actions in the presence of a pre-existing deficiency of this neurotransmitter.

Buspirone differs from benzodiazepines in that it does not inhibit motor coordination or spontaneous motor activity but can produce serotonin syndrome in rats ([Barrett and Witkin 1991](#); [Eison et al. 1991](#)). Unlike benzodiazepines,

buspirone lacks abuse potential and does not impair psychomotor performance alone or in combination with ethanol ([Griffith et al. 1986](#); [Smiley 1987](#); [Sussman and Chow 1988](#)). The behavioral effects of buspirone and benzodiazepines differ somewhat in animal models of anxiety ([Barrett and Witkin 1991](#)) in that buspirone does not uniformly increase punished or conflict responding in rats and monkeys. In pigeons, by contrast, buspirone enhances punished response equivalently to benzodiazepines, a characteristic of 5-HT<sub>1A</sub> receptor agonists such as 8-OH-DPAT, whereas TCAs, SSRIs, opioids, antipsychotics, and psychomotor stimulants do not. Buspirone enhances exploratory and social interaction behavior in rodents, similar to benzodiazepines.

5-HT<sub>1A</sub> agonists are active in animal models of depression. Similar to TCAs and SSRIs, 5-HT<sub>1A</sub> agonists such as 8-OH-DPAT and the azapirones produce antidepressant-like behavior in the forced-swim test in rats ([Wieland and Lucki 1990](#)). This effect occurs in the absence of changes in locomotor activity and is not diminished by pretreatment with the 5-HT synthesis inhibitor pCPA, suggesting that 5-HT<sub>1A</sub> agonists produce an antidepressant response through postsynaptic effects on 5-HT<sub>1A</sub> receptors. Buspirone's activity in preclinical models of depression comports with findings in placebo-controlled trials of buspirone indicative of its antidepressant properties ([Rickels et al. 1991](#); [Robinson et al. 1989a](#)). The buspirone metabolite 1-(2-pyrimidinyl)piperazine (1-PP) is devoid of such activity.

# Pharmacokinetics and Mechanism of Action

---

With oral administration, buspirone undergoes extensive first-pass metabolism by cytochrome P450 (CYP) 3A4 enzymes, with a mean elimination half-life of 3–4 hours ([Gammans and Johnston 1991](#)). Food prolongs the elimination half-life of buspirone, as does hepatic or renal impairment. The pharmacokinetics of buspirone in elderly patients and young adults do not differ ([Gammans et al. 1989](#)).

Buspirone has several metabolites with differing pharmacological activity: 6-hydroxybuspirone (6-OH-Bu), 5-hydroxybuspirone (5-OH-Bu), 8-hydroxybuspirone (8-OH-Bu), and 1-PP. Noradrenergic properties of 1-PP may induce unwanted side effects in patients who have panic attacks or are undergoing benzodiazepine withdrawal. Conversion of buspirone to 6-OH-Bu is the major metabolic pathway in the hepatic clearance of buspirone ([Dockens et al. 2006](#); [Zhu et al. 2005](#)), and bioavailability of 6-OH-Bu is greater than that of the parent drug (19% vs. 1.4% for buspirone; [Wong et al. 2007](#)), significantly contributing to buspirone's therapeutic activity ([Dockens et al. 2006](#)). In vitro, 6-OH-Bu exhibits high affinity (25 nM) and partial agonist activity for the 5-HT<sub>1A</sub> receptor ([Wong et al. 2007](#)).

The anxiolytic effects of buspirone appear to be mediated by its actions on 5-HT receptors in the limbic system ([Eison and Eison 1994](#); [Yocca 1990](#)). In addition to being a 5-HT<sub>1A</sub> agonist, buspirone acts as both a D<sub>2</sub> agonist and a D<sub>2</sub> antagonist in the anterior pituitary, regulating prolactin levels. Buspirone has significant neuroendocrine effects

beyond those related to dopamine receptors. 5-HT<sub>1A</sub> receptors regulate the neuroendocrine hormones, including growth hormone, adrenocorticotrophic hormone, corticosterone, and oxytocin ([Gilbert et al. 1988](#); [Pan and Gilbert 1992](#); [Van de Kar et al. 1985](#); [Vicentic et al. 1998](#)). Buspirone produces dose-dependent increases in rat plasma prolactin levels ([Meltzer and Fleming 1982](#)). Buspirone antagonizes the inhibitory effects of dopamine on prolactin release from the rat pituitary gland in vitro, illustrative of its partial agonist activity at D<sub>2</sub> receptors ([Meltzer et al. 1991](#)). All azapirones decrease body temperature ([Cowen et al. 1990](#); [Meltzer et al. 1991](#)). Buspirone stimulation of prolactin and corticosterone secretion in the rat is enhanced by pCPA, whereas spiperone inhibits buspirone-induced increases in corticosterone secretion ([Meltzer et al. 1991](#)). Pindolol, a 5-HT<sub>1A</sub> antagonist, does not block the buspirone-induced increase in prolactin ([Meltzer et al. 1991](#)). The neuroendocrine effects of buspirone are complex, reflecting properties of both dopamine antagonism and 5-HT<sub>1A</sub> partial agonism.

## Indications and Efficacy

---

### Approved Clinical Indications

#### Generalized Anxiety Disorder

Clinical development of buspirone began after positive findings were reported in a placebo-controlled, proof-of-concept study in anxious patients ([Goldberg and Finnerty](#)

1979). In Phase III placebo-controlled trials comparing buspirone and diazepam, the two anxiolytics had comparable efficacy in patients meeting diagnostic criteria for DSM-II anxiety neurosis (Böhm et al. 1990a; Goldberg and Finnerty 1982; Rickels et al. 1982). In these double-blind, variable-dose titration studies, buspirone or diazepam was given thrice daily at a mean dosage of 20–25 mg/day over 4 weeks.

When the FDA granted marketing approval for buspirone in 1986, a newer DSM classification system, DSM-III (American Psychiatric Association 1980), had replaced anxiety neurosis with the diagnostic category generalized anxiety disorder. Analyses of Hamilton Anxiety Scale (Ham-A; Hamilton 1959) and other symptom ratings were consistent with a diagnosis of DSM-III GAD, and buspirone received FDA approval for the indication of GAD, including anxiety with coexisting depressive symptoms.

Buspirone has a slower onset of therapeutic effect relative to the benzodiazepines (Enkelmann 1991; Pecknold et al. 1989; Rickels 1990). This slower onset is attributable to differences between buspirone and benzodiazepines in relief of somatic anxiety, whereas the two drugs are similar in rate of alleviation of psychic anxiety. Lack of sedation with buspirone also contributes to the perception of a more gradual onset of anxiolysis, similar to that with imipramine (Rickels et al. 1993) and SSRIs (Rickels et al. 2003). With buspirone, relief of somatic anxiety (particularly insomnia) occurs only after psychic anxiety symptoms abate, whereas the immediate-sedating properties of benzodiazepines give the perception of a faster onset of therapeutic benefit.

A longer-term 6-month double-blind comparative trial of buspirone and benzodiazepines confirmed that onset of anxiolytic effects was slower with buspirone than with

clorazepate during the first 4 weeks of treatment ([Rickels et al. 1988](#)). With ongoing treatment, however, the therapeutic response to the two drugs was equivalent. Clinical improvement was maintained over the 6-month study period, and therapeutic tolerance did not develop with either drug. On double-blind termination of treatment at 6 months, several patients who stopped clorazepate abruptly experienced relapse, whereas none relapsed in the buspirone group. The finding that symptom relapse did not occur with abrupt discontinuation of buspirone confirmed conclusions from other investigators ([Fontaine et al. 1984](#); [Noyes et al. 1988](#)) that the rapid return of symptoms after discontinuation of clorazepate was attributable to benzodiazepine withdrawal rather than to a recrudescence of the underlying anxiety disorder.

A benzodiazepine may be indicated as initial therapy for chronically anxious patients; however, longer-term benzodiazepine treatment can lead to physical dependence. Benzodiazepine treatment may be inappropriate for some patients because of the risk of substance abuse or cognitive impairment. When starting a patient on buspirone treatment, one should inform the patient that the drug is less sedating and has a gradual onset of action. Patients can be reassured that buspirone lacks physical dependence liability and does not impair cognition or acquisition of coping skills ([Rickels and Schweizer 1990](#)).

Possible clinical benefit of buspirone on the benzodiazepine withdrawal syndrome was assessed in 15 patients with chronic anxiety who had previously attempted both abrupt and gradual withdrawal of benzodiazepine treatment without success ([Schweizer and Rickels 1986](#)). In this study, addition of buspirone overlapping with tapering of the benzodiazepine dosage did not ameliorate the

symptoms of benzodiazepine withdrawal, and none of the patients could be maintained on buspirone monotherapy after complete withdrawal of benzodiazepine treatment. In other studies, buspirone showed only modest beneficial effects on the benzodiazepine withdrawal syndrome ([Delle Chiaie et al. 1995](#); [DeMartinis et al. 2000](#); [Udelman and Udelman 1990](#)).

Following buspirone's approval by the FDA, several well-controlled efficacy trials in GAD confirmed the drug's significant anxiolytic efficacy ([Enkelmann 1991](#); [Laakmann et al. 1998](#); [Lader and Scotto 1998](#); [Murphy et al. 1989](#); [Pecknold et al. 1989](#); [Scheibe 1996](#)). In a 3-week placebo-controlled comparison trial in 60 patients with anxiety disorder in a general medical setting, [Böhm et al. \(1990a\)](#) found buspirone and the benzodiazepine clobazam to be equally effective and superior to placebo in relieving anxiety.

Long-term follow-up at 40 months of patients who previously completed a 6-month controlled trial comparing buspirone and clorazepate revealed that none of the buspirone-treated patients needed anxiolytic medication, whereas more than 50% of the patients treated with clorazepate required continuation anxiolytic therapy ([Rickels and Schweizer 1990](#)).

Buspirone was evaluated in elderly patients with anxiety symptoms in a double-blind, placebo-controlled trial and was found to be both safe and effective ([Böhm et al. 1990b](#)). Buspirone's lack of sedation and sparing of cognition and memory were a strong therapeutic advantage in this population. Meta-analyses of several multicenter trials of buspirone in elderly patients also showed buspirone to be safe and well tolerated ([Ritchie and Cox 1993](#); [Robinson et al. 1988](#)).

Buspirone treatment also was assessed in patients with panic disorder in placebo-controlled trials ([Pohl et al. 1989](#); [Sheehan et al. 1990](#)). Buspirone does not diminish panic attacks. However, a meta-analysis of double-blind three-arm multicenter trials in panic disorder comparing buspirone, imipramine, and placebo treatment found that both imipramine and buspirone improved anxiety symptoms ([Robinson et al. 1989b](#)). Buspirone's lack of effect on number of panic attacks is unsurprising in light of preclinical evidence that buspirone increases firing rates in the locus coeruleus ([Eison and Temple 1986](#)) and causes noradrenergic hyperactivity ([Sanghera et al. 1982](#)), both manifestations of panic disorder.

### **Mixed Anxiety-Depression**

In initial trials of patients with anxiety disorder and subsyndromal depression, depressive symptoms improved significantly with buspirone treatment ([Feighner et al. 1982](#); [Goldberg and Finnerty 1979](#)). This finding fostered interest in the potential antidepressant properties of buspirone because of the high comorbidity of GAD and MDD ([Brown and Barlow 1992](#)) and led to the speculation that GAD and MDD may represent differing clinical manifestations of a single underlying diathesis. Genetic studies in patients with MDD and GAD suggest that genetic vulnerability for the two disorders is largely shared ([Kendler et al. 1992](#)). The relationship of MDD and GAD and their clinical treatment have been reviewed ([Kendler et al. 1992](#); [Roy-Byrne 2008](#)).

Buspirone treatment of patients with MDD associated with significant anxiety symptoms was assessed in placebo-controlled trials ([Rickels et al. 1991](#); [Robinson et al. 1989a, 1990](#)). Patients with MDD were eligible for inclusion in

these studies if their Hamilton Rating Scale for Depression (Ham-D; [Hamilton 1960](#)) and Ham-A scores were  $\geq 18$  and  $\geq 15$ , respectively. The daily dosage ranged up to a maximum of buspirone 90 mg/day (mean  $\sim 50$  mg/day). Buspirone treatment was superior to placebo treatment, with a global response rate (based on Clinical Global Impressions-Improvement [CGI-I] scale scores) of 70% for buspirone and 35% for placebo ([Rickels et al. 1991](#)). In a subsequent placebo-controlled study involving 177 geriatric depressed outpatients, [Schweizer et al. \(1998\)](#) compared buspirone and imipramine treatment for 8 weeks. There was a statistically significant treatment effect for both buspirone (mean daily dosage,  $\sim 50$  mg) and imipramine (mean daily dosage,  $\sim 90$  mg) compared with placebo treatment.

Buspirone augmentation of SSRI treatment of partially responding depressed patients leads to further improvement ([Dimitriou and Dimitriou 1998](#); [Gonul et al. 1999](#); [Jacobsen 1991](#); [Landén et al. 1998](#)). These findings were confirmed in a report of the Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) program. Patients who initially did not respond to an adequate therapeutic trial with an SSRI responded when their medication was augmented with either buspirone or bupropion ([Trivedi et al. 2006](#)). In an exploratory double-blind, placebo-controlled study in patients with an MDD diagnosis, [Fava et al. \(2012\)](#) reported significant antidepressant efficacy for combined buspirone 15 mg and melatonin slow release (SR) 3 mg. This preliminary finding is mentioned only to indicate persisting interest in buspirone as a potential augmentor of other antidepressants, not as a treatment recommendation.

We speculate that had buspirone's sponsor pursued a depression rather than a GAD indication, buspirone might well have become the first 5-HT<sub>1A</sub> partial agonist developed as an antidepressant. At present, however, buspirone exists in the shadow of numerous approved antidepressant drugs with high clinical exposure and promotion. The fact that the product life cycle of buspirone (BuSpar) was relatively short, whereas SSRIs with longer patent lives had already received a clinical indication for GAD, served to restrain buspirone's sponsor from seeking an approved indication for MDD and limited the drug's approved indication to treatment of anxiety and anxiety with associated depression.

## Nonapproved Clinical Indications

Potential clinical indications for buspirone treatment unapproved by the FDA were reviewed by [Rickels et al. \(2003\)](#); selected studies are mentioned here.

### **Substance-Related Disorders**

Several placebo-controlled trials have demonstrated the usefulness of buspirone in facilitating smoking cessation ([Hilleman et al. 1992](#); [West et al. 1991](#)), although its main effect was in smokers who were also highly anxious ([Cinciripini et al. 1995](#)).

Buspirone has been assessed in several double-blind, placebo-controlled trials involving anxious outpatients with coexisting alcohol use disorder and found to be efficacious ([Rickels et al. 2003](#)). Buspirone's lack of abuse potential and negligible additive effects on psychomotor and cognitive functions when coadministered with alcohol

([Mattila et al. 1982](#)) make it a useful addition to pharmacotherapies for alcohol-related disorders.

Buspirone was found to ameliorate symptoms of opioid withdrawal in a placebo-controlled trial ([Buydens-Branchey et al. 2005](#)).

Although elevations in synaptic dopamine levels have been demonstrated to play a pivotal role in the reinforcing effects of cocaine, neither D<sub>1</sub> nor D<sub>2</sub> receptor antagonists have proved clinically effective in cocaine addiction. Speculating that dopamine D<sub>3</sub> and D<sub>4</sub> receptors might be possible targets for pharmacotherapy, [Bergman et al. \(2013\)](#) undertook an investigation of buspirone, which has been found to bind with high affinity to these receptors, to evaluate its functional effects in animal models. On the basis of their finding that buspirone produced a downward shift in the dose–effect function for cocaine-maintained behavior, Bergman and colleagues proposed that buspirone be evaluated for its utility in the management of cocaine addiction. However, in a 16-week double-blind multicenter pilot trial, [Winhusen et al. \(2014\)](#) found that buspirone at dosages titrated up to 60 mg/day was not beneficial in preventing relapse to cocaine use.

A small placebo-controlled pilot trial originally found buspirone to be significantly superior to placebo on several measures in the treatment of DSM-IV ([American Psychiatric Association 1994](#)) marijuana dependence ([McRae-Clark et al. 2009](#)). However, a 12-week trial with a larger sample size found no advantage for buspirone (titrated to 60 mg/day) over placebo in reducing cannabis use ([McRae-Clark et al. 2015](#)).

## **Adjunctive Use in Schizophrenia**

Several studies have evaluated the adjunctive use of buspirone in patients with chronic schizophrenia being treated with typical and atypical antipsychotic drugs. In a 6-month placebo-controlled trial of adjunctive buspirone 30 mg/day in patients being maintained on an atypical antipsychotic drug, Sumiyoshi [et al. \(2007\)](#) observed no improvement in Brief Psychiatric Rating Scale scores, although they noted improved recall on one secondary outcome measure, the Verbal Learning subscale. Two placebo-controlled pilot trials of limited size by an Iranian group found that adjunctive treatment with buspirone was beneficial in improving negative symptoms in patients with chronic schizophrenia maintained on antipsychotic drugs ([Ghaleiha et al. 2010](#); [Sheikhmoonesi et al. 2015](#)), a finding warranting further study.

### **Adjunctive Use in Autism Spectrum Disorder**

Buspirone treatment has been assessed in autistic patients. In an 8-week placebo-controlled trial of adjunctive buspirone during risperidone maintenance treatment of 40 children and adolescents with autism spectrum disorder, [Ghanizadeh and Ayoobzadehshirazi \(2015\)](#) observed a 30% decline in Aberrant Behavior Checklist-Community Rating Scale irritability subscale scores in 13 of the 16 buspirone patients versus 7 of the 18 placebo patients, a significant treatment effect. In a three-arm, 24-week placebo-controlled trial ( $n=166$ ), [Chugani et al. \(2016\)](#) assessed the safety and efficacy of low-dosage buspirone in children with autism spectrum disorder. The buspirone 2.5 mg bid group showed significant improvement in irritability ratings, whereas the 5.0 mg bid group did not differ from the placebo group. This finding warrants further investigation.

## Other Disorders

Buspirone's utility has been explored in a variety of other disorders. Two small double-blind clinical trials indicated modest efficacy for buspirone over placebo in the symptomatic treatment of premenstrual syndrome ([Brown et al. 1990](#); [Rickels et al. 1989](#)). [Lee et al. \(2005\)](#), in a placebo-controlled study, showed beneficial effects of buspirone in migraine patients with anxiety symptoms. Buspirone was evaluated under double-blind conditions in Alzheimer's patients with aggressive behavior and agitation ([Cantillon et al. 1996](#)) and was found to be superior to haloperidol. In a randomized double-blind study, buspirone was as effective as methylphenidate in treating aggressive behavior in attention-deficit/hyperactivity disorder ([Davari-Ashtiani et al. 2010](#)). Studies in animal models and clinical trials indicate that buspirone may be useful in treating tardive dyskinesia ([Howland 2011](#)) as well as L-dopa-induced and graft-induced dyskinesias of Parkinson's disease ([Loane and Politis 2012](#)).

---

## Dosage and Administration

---

The recommended buspirone dosage for treatment of GAD is 15–20 mg/day initially, prescribed in divided doses, with increases to 30 mg/day if indicated and a maximum dosage of 60 mg/day. It should be mentioned that in the double-blind, placebo-controlled MDD trials described earlier (see the section “Mixed Anxiety-Depression”), the maximum dosage was 90 mg/day ([Rickels et al. 1991](#); [Robinson et al. 1989a, 1990](#)). Therefore, higher buspirone dosages than those prescribed for anxiety disorders may be required in

the treatment of MDD, either as monotherapy or as augmentation of an SSRI.

Therapeutic response to buspirone differs in anxious patients naïve to benzodiazepine treatment compared with patients recently treated with a benzodiazepine ([DeMartinis et al. 2000](#); [Schweizer and Rickels 1986](#)). Findings of placebo-controlled efficacy trials showed that GAD patients with either no prior benzodiazepine treatment or temporally remote benzodiazepine treatment (>6 months previously) experienced greater improvement with buspirone therapy than did patients who either were currently receiving or had recently completed treatment with a benzodiazepine. This diminished therapeutic response may reflect a subclinical benzodiazepine withdrawal syndrome (possibly exacerbated by buspirone's 1-PP metabolite). Directly switching from SSRI treatment to buspirone is not problematic.

---

## Side Effects and Toxicology

---

[Newton et al. \(1986\)](#), summarizing data from 17 clinical trials, noted the incidence of frequently reported adverse effects experienced during buspirone treatment: dizziness (12%), drowsiness (10%), nausea (8%), headache (6%), nervousness (5%), fatigue (4%), insomnia (3%), light-headedness (3%), dry mouth (3%), and excitement (2%). Buspirone lacks abuse potential, unlike alcohol and the benzodiazepines ([Balster 1991](#)). Psychomotor function studies, including evaluation of complex motor driving skills and memory tasks, have documented buspirone's absence of impairment liability in these domains ([Boulenger et al.](#)

1989; Greenblatt et al. 1994; Lucki et al. 1987; Smiley and Moskowitz 1986). Buspirone does not inhibit CYP enzymes, although it does cause modest elevations of haloperidol and cyclosporin A levels. Buspirone has few significant pharmacodynamic interactions with other psychotropic drugs, apart from a potential risk of serotonin syndrome in combination with monoamine oxidase inhibitors. Since buspirone's introduction into clinical medicine, no deaths attributable solely to buspirone overdose have been reported. Buspirone remains an unusually safe and well-tolerated anxiolytic with no abuse liability.

---

## Conclusion

---

Discovery of the 5-HT<sub>1A</sub> receptor was instrumental in linking modulation of 5-HT neurotransmission with anxiety disorders. Buspirone, a selective partial agonist of the 5-HT<sub>1A</sub> receptor, is the only drug in this class of antianxiety agents approved for the treatment of GAD and anxiety with associated depressive symptoms.

## CHAPTER 24

# Classic Antipsychotic Medications

### History and Discovery

---

Prior to the introduction of classic antipsychotic medications in the 1950s, treatment for psychotic disorders primarily consisted of institutional confinement and supportive care with minimal control of psychotic symptoms. The discovery of chlorpromazine, the first of the “classic” antipsychotics, was serendipitous and owes much to the observations of a French surgeon, Henri Laborit, who noted that chlorpromazine, when used as an adjunct to anesthesia, calmed patients significantly following surgery. Laborit recommended its use to two French psychiatrists, Jean Delay and Pierre Deniker, who used it successfully in psychotic patients. Heinz Lehmann was the first to use chlorpromazine in North America (in Montreal, Canada). In the early 1960s, the first large-scale placebo-controlled trials were conducted within the U.S. Veterans Administration system.

After the successes of chlorpromazine, numerous other phenothiazines were synthesized by modifying the side chains on the phenothiazine rings. Subsequently, several nonphenothiazine antipsychotics, such as haloperidol, were introduced. The last of these drugs approved by the U.S. Food and Drug Administration (FDA) was molindone, introduced in 1975. Of 51 classic antipsychotic drugs (representing eight different chemical classes) available in the world, 9 are currently available in the United States.

The ability of chlorpromazine and other conventional antipsychotics to suppress psychotic symptoms (delusions, hallucinations, and disorganization) had a profound impact on chronically hospitalized psychiatric populations worldwide. Massive numbers of psychiatric patients were discharged from state hospitals to the community. This period of deinstitutionalization led to a decrease in the number of patients in state and county mental hospitals in the United States from 559,000 in 1955 to 338,000 in 1970 to 107,000 in 1988, an 80% decrease over 30 years. Initially, this led to enthusiasm about the possibility that patients with schizophrenia and other psychoses would be able to function well in the community. However, it soon became apparent that improvement with antipsychotic treatment was incomplete. In addition, poor treatment adherence—with subsequent relapses—led to frequent rehospitalization (i.e., the “revolving door” phenomenon).

As psychiatrists began using chlorpromazine, they observed that treated patients frequently manifested signs and symptoms of parkinsonism. Along with other side effects such as dystonia and akathisia, these symptoms are collectively referred to as

*extrapyramidal side effects* (EPS). Because of the high prevalence of these movement disorders in patients receiving antipsychotic treatment, many psychiatrists believed EPS to be an unavoidable accompaniment of antipsychotic action; in fact, the onset of some EPS was considered to indicate the minimal effective antipsychotic dose (i.e., the “neuroleptic threshold”). The first report of persistent orobuccal movements (later labeled *tardive dyskinesia*) came from France in 1959. The pervasiveness of debilitating short-term and long-term motor side effects associated with classic antipsychotic drugs led to a search for agents that would be at least as efficacious but without the risk of EPS.

Clozapine, a dibenzodiazepine synthesized in 1959, was the first antipsychotic drug without EPS (i.e., atypical). It was initially marketed in Europe in 1972 but was withdrawn in some countries in 1975 after several reports of fatalities secondary to agranulocytosis. Clozapine was not introduced in the United States until 1989, after convincing studies demonstrated its efficacy in antipsychotic-refractory schizophrenia. Other atypical agents (also referred to as second-generation antipsychotics [SGAs]) have been launched in the past 15 years and are reported to be associated with lower levels of EPS and a broader spectrum of efficacy; of the 16 SGAs currently being marketed, 12 are available in the United States (see [Chapters 25–34](#) in this volume). Since the introduction of these newer agents, use of the classic antipsychotics (also referred to as traditional, conventional, or first-generation antipsychotics [FGAs]) has declined, especially in the United States—FGAs currently aggregate approximately 5% of all antipsychotic prescriptions in the country. Results of several government-sponsored effectiveness studies—for example, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE)—in the past decade have challenged the prevailing worldview of the greater effectiveness of SGAs over FGAs and have reinvigorated interest in the utility and clinical applicability of classic antipsychotics.

## Structure-Activity Relations

### Phenothiazines

Members of the phenothiazine class of classic antipsychotics share the same basic phenothiazine ring but differ in substitutions at both their R1 and R2 positions ([Figure 24-1](#)). Based on the side chain attached to the nitrogen atom in the middle ring (R1), the phenothiazines are further subdivided into three subtypes: aliphatic, piperidine, and piperazine phenothiazines.

### Aliphatic Phenothiazines

The aliphatic phenothiazines share a dimethylamide substitution at their tenth carbon. Chlorpromazine (Thorazine or Largactil) is the prototypical member of this class and remains the aliphatic phenothiazine most widely used throughout the world. With a chlorine atom attached to its second carbon, chlorpromazine is heavily sedating because of its high level of anticholinergic, anti- $\alpha$ -adrenergic, and antihistaminergic actions.

### Piperidine Phenothiazines

Piperidine phenothiazines—for example, thioridazine (Mellaril) and its metabolite, mesoridazine (Serentil)—are named for the presence of a piperidine ring at their tenth carbon. Although members of this group have similar efficacy and side effects compared with aliphatic phenothiazines, they are notable for having a less potent effect on nigrostriatal dopamine<sub>2</sub> ( $D_2$ ) receptors and a higher level of anticholinergic activity; consequently they are associated with a lower frequency of EPS. The use of these agents has been virtually extinguished by a black box warning about significant QTc prolongation that was added to their product label in 2000.

## Piperazine Phenothiazines

With a substitution of a piperazine group at the tenth carbon of a phenothiazine, the piperazines have greatly increased dopamine type 2 ( $D_2$ ) receptor blockade and a lower affinity for muscarinic,  $\alpha$ -adrenergic, and histaminergic receptors. Some of the most potent conventional antipsychotics available in the United States, including fluphenazine (Prolixin), perphenazine (Trilafon), and trifluoperazine (Stelazine), belong to this class. The well-known antiemetic prochlorperazine (Compazine) is also part of this class; although approved for the treatment of psychosis, it is rarely utilized as an antipsychotic.

## Thioxanthenes

Structurally and pharmacologically similar to the phenothiazines, the thioxanthenes also differ widely in their pharmacological profiles based on similar side-chain substitutions (see [Figure 24-1](#)). For instance, chlorprothixene shares the same dimethylamide and chloride substitution as chlorpromazine, with which it also shares its pharmacological profile. Thiothixene (Navane) has both a piperazine side chain and a strongly electrophilic substitution [ $SO_2N(CH_3)CH_3$ ], thus sharing the pharmacological profile of the piperazines.

## Butyrophenones

The butyrophenone class has a piperidine ring with a three-carbon chain ending in a carbonyl-substituted p-fluorobenzene ring. Haloperidol, arguably the best-known classic antipsychotic, is the most widely used member of this class. Haloperidol and other members of this class are strong dopamine receptor antagonists and show little antimuscarinic, antihistaminergic, and antiadrenergic activity.

## Dibenzoxazepines

Loxapine, the only FDA-approved agent within the dibenzoxazepine class, is composed of a tricyclic ring structure with a seven-member central ring. It has a piperazine side chain and chlorine at position R2 (see [Figure 24-1](#)). It exhibits an intermediate level of  $D_2$  blockade, as well as some serotonin<sub>2</sub> (5-HT<sub>2</sub>) antagonism. Its side-effect profile is characterized by intermediate sedation and autonomic effects. Loxapine has the distinction of being the most “atypical” of the classic antipsychotics because it is structurally similar to the dibenzodiazepine clozapine. Another notable feature of loxapine is that one of its metabolites, amoxapine, is marketed as an antidepressant.

## Dihydroindoles

Molindone is the only member of the dihydroindoles available in the United States. Sharing a similar structure with the indoleamines (see [Figure 24-1](#)), such as serotonin, molindone has the distinction of being the only classic antipsychotic not associated with any weight gain or a lowering of the seizure threshold.

## Diphenylbutylpiperidines

Pimozide, the only agent within the diphenyl-butyl-piperidine class available in the United States, is approved only for the treatment of Tourette syndrome and has the distinction of possessing the highest selectivity and potency for dopamine D<sub>2</sub> receptors among the conventional antipsychotics. It significantly prolongs the QTc interval, and this has limited its utilization. Derived from benperidol, pimozide shares many characteristics of the butyrophenones (see [Figure 24-1](#)).

## Benzamides and Iminodibenzyl Agents

Sulpiride, the prototypical substituted benzamide, is a relatively selective dopamine D<sub>2</sub> antagonist and lacks significant activity on cholinergic, histaminergic, or noradrenergic receptors. Because of this relative selectivity and a lower propensity to cause EPS, sulpiride is one of the more common classic antipsychotics utilized in Europe. No classic antipsychotic agent from either the benzamide or the iminodibenzyl class is available in the United States.

## Pharmacological Profile

---

The classic conventional antipsychotic drugs have a multitude of effects on various physiological variables through their actions on different neurotransmitter systems. The antipsychotic effects of these agents are believed to occur primarily through antagonism of D<sub>2</sub>-type dopaminergic receptors. Therapeutic and adverse effects of D<sub>2</sub> antagonism have been conceptualized in the context of the major dopaminergic tracts present in the brain, which include the mesocortical, mesolimbic (A10), tuberoinfundibular (A12), and nigrostriatal (A8 and A9) tracts.

The effect of D<sub>2</sub> receptor blockade on the mesolimbic dopaminergic systems is believed to represent the putative mechanism of action of conventional antipsychotics, but D<sub>2</sub> blockade in other tracts is believed to result in a number of adverse cognitive and behavioral side effects. Such side effects are frequently observed in both animals and human subjects. D<sub>2</sub> receptor antagonism in the mesocortical dopaminergic pathway leads to a blunting of cognition (bradyphrenia) and avolition-apathy (sometimes referred to as the *neuroleptic-induced deficit syndrome*), which can be difficult to differentiate from the primary negative symptoms of schizophrenic illness itself.

Blockade of the tuberoinfundibular tract projecting to the hypothalamus and pituitary gland results in multiple neuroendocrine side effects processed through the pituitary gland. Although dopamine is involved in enhancing the release of most pituitary hormones, it is actually responsible for the tonic inhibition of prolactin release. With significant dopaminergic blockade of the tuberoinfundibular tract, prolactin release is no longer prevented, and the release of other pituitary hormones is no longer enhanced. High levels of prolactin combined with decreased levels of follicle-stimulating hormone and luteinizing hormone often result in amenorrhea, galactorrhea, gynecomastia, decreased bone density, impaired libido, and erectile dysfunction.

High levels (exceeding 78%) of D<sub>2</sub> dopaminergic blockade within the nigrostriatal system, which projects to the basal ganglia and caudate, produce some of the most undesirable side effects of conventional antipsychotics. Movement disorders or EPS such as akathisia, rigidity, and hypokinesia were once believed to be necessary “evidence” of a therapeutic antipsychotic dosage. However, the advent of the new-generation

antipsychotics that are associated with minimal EPS conclusively dispensed with this misconception. At higher levels of D<sub>2</sub> blockade, one may also observe dystonia, catalepsy, and a rigid, immobile catatonic state.

Classic antipsychotic agents have varying degrees of activity at serotonergic, cholinergic, noradrenergic, histaminergic, and other nondopaminergic receptors. Although it is unclear whether any of these activities contribute to or interfere with their effectiveness in the treatment of psychotic symptoms, they clearly result in a variety of adverse effects. Because of differences in the pharmacological activity of different classic antipsychotic agents at these receptors, there are predictable differences in their side-effect profiles.

## Pharmacokinetics

Generally, the pharmacokinetic profiles of the conventional antipsychotics remain poorly understood. Even for some of the more extensively studied agents, many hundreds of potential metabolites remain undiscovered, and the physiological activity of several metabolites has yet to be adequately defined. Nonetheless, certain general statements can be made concerning the classic antipsychotics as a group.

## Administration and Absorption

Many of the conventional antipsychotics are available in both oral and intramuscular formulations. Although relatively common in the past, intravenous usage of parenteral formulations of antipsychotics is not FDA-approved. Peak plasma levels with oral preparations are generally reached in 1–4 hours, with these levels being reached slightly more rapidly with liquid concentrates. Oral preparations are extensively metabolized in the liver during their first pass through portal circulation by undergoing a range of transformations, including glucuronidation, oxidation, reduction, and methylation. Steady-state levels are reached in a period of four to five times the half-life of the drug in question.

Intramuscular administration results in faster, more predictable absorption, with peak plasma levels in 30–60 minutes and clinical efficacy as rapidly as 15 minutes. With intramuscular or intravenous administration, plasma levels may be as much as four times the levels of the oral route because of circumvention of the hepatic first-pass metabolism.

Although 10 classic antipsychotics are available in a long-acting (depot) formulation around the world, haloperidol and fluphenazine are the only classic antipsychotics currently available in such a formulation in the United States. The currently available decanoate forms of both haloperidol and fluphenazine are administered through injection into a major muscle, and the drug is slowly released to the bloodstream over time. As the esterified version of the drug diffuses into other tissues, the ester chain is hydrolyzed, resulting in the smooth release of the drug in question. Fluphenazine decanoate can be given every 2–3 weeks on the basis of its half-life of 7–10 days, whereas haloperidol decanoate may be given every 4 weeks because of its longer half-life. The bioavailability of intramuscular relative to oral administration is twofold greater.

## Distribution

Most of the conventional antipsychotics are highly protein bound (85%–90%). This feature is of importance when other highly protein-bound medications are used concomitantly

because of the risk of increasing levels of free or unbound drugs into the toxic range. The antipsychotic drugs are highly lipophilic, which allows unbound portions of the drug to readily cross the blood-brain barrier, with concentrations twofold higher in the brain than in the peripheral circulation. The drugs also readily cross the placenta to the fetus in pregnancy.

## Metabolism

The conventional antipsychotics are metabolized in the liver by hydroxylation and demethylation to forms that are more soluble and readily excreted by the kidneys and in the feces. Many of these compounds undergo further glucuronidation and remain active as dopamine receptor antagonists. Because of the many active metabolites of the antipsychotic agents, it has not been possible to obtain meaningful correlations between plasma levels and clinical response. Variables such as age, genetic variability among individuals, and coadministration of other drugs cause plasma levels to vary 10- to 20-fold across individuals. The majority of conventional antipsychotics are metabolized by the cytochrome P450 (CYP) enzyme subfamilies. Since CYP2D6 is important for the metabolism of many of these antipsychotics, genetic variation in the rate of 2D6 metabolism should be considered. CYP1A2 and 3A4 subfamily enzymes are also involved in the metabolism of some classic antipsychotics, and this may be relevant to understanding drug-drug interactions of those agents.

## Excretion

The major routes of excretion of the classic antipsychotics are through urine and feces by way of bile. These drugs are also excreted in sweat, saliva, tears, and breast milk. Elimination half-life varies from 18 to 40 hours for these drugs. Lower doses of antipsychotics are generally needed in elderly patients because of decreased renal clearance. Because of the long elimination half-lives of the classic antipsychotics, once-a-day dosing is possible for each of these agents following stabilization.

## Mechanism of Action

---

Dopamine has been at the center of neurobiological theories of psychosis for the past half-century, and even today, all agents approved as antipsychotics share the single common attribute of dopamine D<sub>2</sub> receptor antagonism. Amphetamine intoxication served as a drug-induced model of the positive symptoms of schizophrenia. Drugs that blocked dopaminergic receptors, specifically the D<sub>2</sub> receptor, were noted to have greater efficacy and potency as antipsychotics. Since dopaminergic agonists exacerbate psychosis and dopaminergic blockade treats it, dopamine has held central importance in our conceptualization of the neuropharmacology of schizophrenia.

## Indications and Efficacy

---

# Schizophrenia and Schizoaffective Disorder

Classic antipsychotics are best known for the acute and maintenance treatment of the psychotic (also known as positive) symptoms of schizophrenia and schizoaffective disorder. The major putative mechanism of action is through D<sub>2</sub> blockade of the mesolimbic tract. In many individuals, this blockade results in a measurable decrease in the positive symptoms of schizophrenia, including hallucinations, delusions, and disorganization ([Tandon et al. 2010, 2013](#)). However, negative and cognitive symptoms of schizophrenia respond less robustly. In fact, they may be worsened by blockade of mesocortical tracts that play roles in cognition and hedonic reinforcement.

The failure to improve the negative symptoms of schizophrenia is one of the major drawbacks of the classic antipsychotics. In fact, the EPS induced by the FGAs can worsen negative and cognitive symptoms by inducing bradykinesia and bradyphrenia. Another major limitation is the lack of improvement of positive symptoms (i.e., refractoriness) in about 25% of schizophrenia patients and partial response (i.e., treatment resistance) in another 25%.

## Substance-Induced Psychosis

As noted previously, conventional agents can reverse the psychosis associated with acute and chronic amphetamine intoxication as well as that associated with cocaine use. However, the risk of acute dystonia must be considered in these populations, as dopamine receptor downregulation is common, resulting in greater sensitivity to rapid D<sub>2</sub> blockade. Results in treatment of psychosis secondary to drugs acting in non-dopaminergic mechanisms (such as hallucinogens) are less satisfactory, although there may be some role for the classic antipsychotics in treating phencyclidine (PCP) psychosis.

## Personality Disorders

Although any personality disorder can be associated with transient psychotic features emerging under stressful conditions, Cluster B disorders are most often associated with this phenomenon. Treatment for transient psychotic episodes has included short-term use of low doses of a high-potency antipsychotic. Although some symptoms of personality disorders may be amenable to such pharmacological treatment, long-term conventional antipsychotic treatment is not recommended.

## Mood Disorders

The utility of antipsychotic agents in the treatment of mood disorders with psychotic features is well known. However, their utility in the treatment of nonpsychotic depression and bipolar disorder is described as well. Several conventional antipsychotics (such as thioridazine) are FDA approved for the treatment of depression and anxiety without overt psychosis. However, they are no longer used for this purpose because of the availability of other, more effective and better-tolerated agents. The utility of conventional agents as adjuncts to mood stabilizers in the treatment of patients with bipolar and related disorders has been well described, both in the acute management of mania and in the maintenance treatment of bipolar disorder with severe mood disturbance and/or psychotic features.

However, the newer atypical antipsychotics have largely replaced conventional antipsychotics in the management of bipolar disorder.

## Tourette Syndrome
